

Data Structures - Test 1

Question 1. (4 points) Consider the following Python code.

```
for i in range(n*n):
    j = 1
    while j < n:
        print (i, j)
        j = j * 2
```

What is the big-oh notation $O()$ for this code segment in terms of n ?

Question 2. (4 points) Consider the following Python code.

```
i = 1
while i < n:
    for j in range(n):
        print(j)

    for k in range(n):
        print(k)

    i = i * 2
```

What is the big-oh notation $O()$ for this code segment in terms of n ?

Question 3. (4 points) Consider the following Python code.

```
def main(n):
    for i in range(n):
        doSomething(n)

def doSomething(n):
    for k in range(n):
        doMore(n)

def doMore(n):
    for k in range(n):
        print(k)

main(n)
```

What is the big-oh notation $O()$ for this code segment in terms of n ?

Question 4. (8 points) Suppose a $O(n^5)$ algorithm takes 10 seconds when $n = 100$. How long would you expect the algorithm to run when $n = 1,000$?

Question 5. (5 points) Why should you design a program instead of “jumping in” and start by writing code?

Question 6. A Deque (pronounced “Deck”) is a linear data structure which behaves like a double-ended queue, i.e., it allows adding or removing items from either the front or the rear of the Deque. One possible implementation of a Deque would be to use a built-in Python list to store the Deque items such that

- the **rear** item is **always stored at index 0**,
- the front item is always at index $\text{len}(\text{self}._items)-1$ or -1

a) (6 points) Complete the big-oh $O()$, for each Deque operation, assuming the above implementation. Let n be the number of items in the Deque.

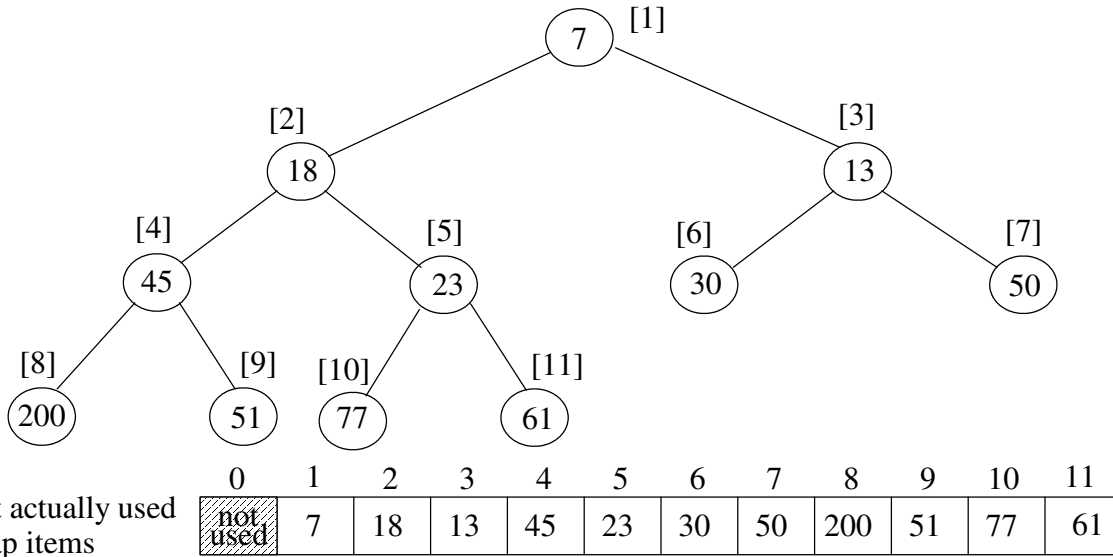

<code>isEmpty</code>	<code>addRear</code>	<code>removeRear</code>	<code>addFront</code>	<code>removeFront</code>	<code>size</code>

b) (9 points) Complete the method for the `removeRear` operation including the precondition check.

```
def removeRear(self):
    """Removes and returns the rear item of the Deque
    Precondition: the Deque is not empty.
    Postcondition: Rear item is removed from the Deque and returned"""
```

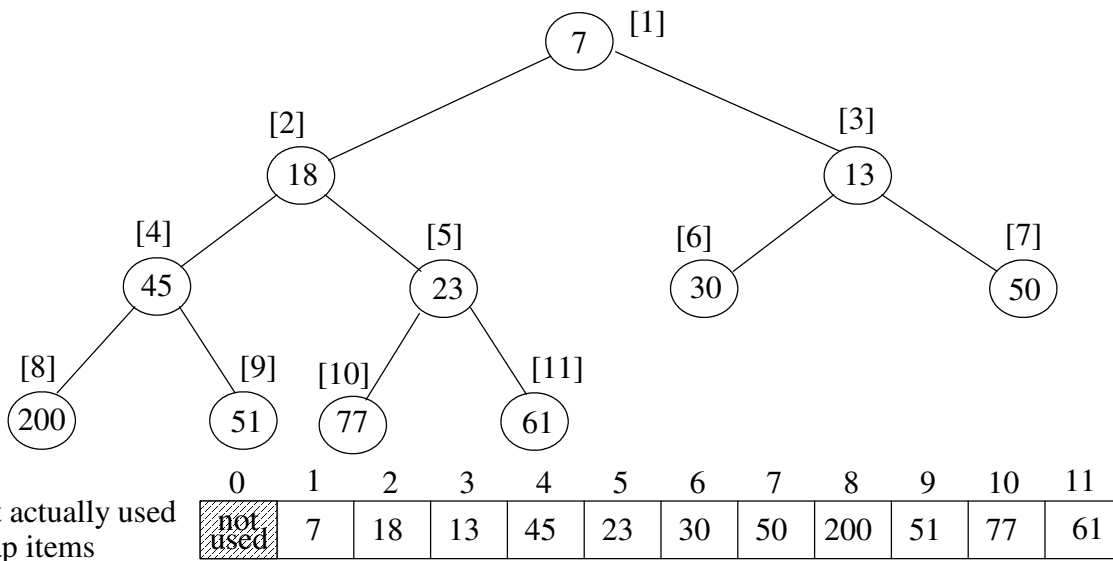

c) (5 points) Suggest an alternate Deque implementation to speed up some of its operations.

Question 7. Consider the binary heap approach to implement a priority queue. A Python list is used to store a *complete binary tree* (a full tree with any additional leaves as far left as possible) with the items being arranged by *heap-order property*, i.e., each node is \leq either of its children. An example of a *min* heap “viewed” as a complete binary tree would be:

- a) (3 points) For the above heap, the list indexes are indicated in []'s. For a node at index i , what is the index of:
 - its left child if it exists:
 - its right child if it exists:
 - its parent if it exists:
- b) (7 points) What would the above heap look like after inserting 12 and then 25 (show the changes on above tree)
- c) (3 points) What is the big-oh notation for inserting a new item in the heap?

Now consider the `delMin` operation that removes and returns the minimum item.

- d) (2 point) What item would `delMin` remove and return from the above heap?
- e) (7 points) What would the above heap look like after `delMin`? (show the changes on above tree)
- f) (3 points) What is the big-oh notation for `delMin`?

Question 8. The textbook's **Ordered list** ADT uses a singly-linked list implementation. I added the `_size` and `_tail` attributes:

a) (15 points) The `add(item)` method adds the `item` to the list. Recall that the textbook's implementation, cannot contain duplicate items!!! Thus, the precondition is that `item` is not already in the list. Complete the `add(item)` method code including the precondition check.

```

class OrderedList(object):
    def __init__(self):
        self._head = None
        self._size = 0
        self._tail = None

    def add(self, item):

class Node:
    def __init__(self, initdata):
        self.data = initdata
        self.next = None

    def getData(self):
        return self.data

    def getNext(self):
        return self.next

    def setData(self, newdata):
        self.data = newdata

    def setNext(self, newnext):
        self.next = newnext
    
```

b) (10 points) Assuming the ordered list ADT described above **does not allow duplicate items**. Complete the big-oh $O()$ for each operation. Let n be the number of items in the list.

<code>add(item)</code>	<code>pop()</code> removes and returns tail item	<code>length()</code> returns number of items in the list	<code>remove(item)</code> removes the item from the list	<code>index(item)</code> returns the position of item in the list
