

Control Statements: - the body of control statements are indented and there is NO other "end" ("}") marker

if statements: An if statement allows code to be executed or not based on the result of a comparison. If the condition evaluates to True, then the statements of the **indented body** is executed. If the condition is False, then the body is skipped. The syntax of if statements is:

<pre>if <condition>: statement₁ statement₂ statement₃</pre>	<pre>if <condition>: statement_{T1} statement_{T2} else: statement_{F1} statement_{F2}</pre>	<pre>if <condition>: statement_{T1} statement_{T2} elif <condition2>: statement statement else: statement_{F1} statement_{F2}</pre>
--	--	---

Typically, the condition involves comparing “stuff” using relational operators (<, >, ==, <=, >=, !=).

Complex conditions might involve several comparisons combined using Boolean operators: not, or, and. For example, we might want to print “Your grade is B.” if the variable score is less than 90, but greater than or equal to 80.

```
if score < 90 and score >= 80:
    print( "Your grade is B." )
```

The precedence for mathematical operators, Boolean operators, and comparisons are given in the table.

	<u>Operator(s)</u>
highest	** (exponential)
↑	+, - (unary pos. & neg.)
	*, /, % (rem), // (int div)
	+, - (add, sub)
	<, >, ==, <=, >=, !=, <>, is, is not
	not
	and
	or
lowest	= (assignment)

for loop: the for loop iterates once for each item in some sequence type (i.e, list, tuple, string).

<pre>for value in [1, 3, 9, 7]: print(value)</pre>	<pre>for character in 'house': print(character)</pre>
--	---

The for loop iterates over an iterable data-structure object (list, string, dictionary) or a range object created by the built-in range function which generate each value one at a time for each iteration of the loop. The syntax of: range([start,] end, [, step]), where [] are used to denote optional parameters.

Some examples:

- range(5) generates the sequence of values: 0, 1, 2, 3, 4
- range(2, 7) generates the sequence of values: 2, 3, 4, 5, 6
- range(10, 2, -1) generates the sequence of values: 10, 9, 8, 7, 6, 5, 4, 3

For example:

```
for count in range(1,6):
    print( count, end="  " )
print("\nDone")
```

1 2 3 4 5 Done

)
while loop: A while statement allows code to be executed repeated (zero or more times) as long as the condition evaluates to True. The syntax of a while statement is:

```
while <condition>:
    statement1
    statement2
    statement3
```

An *infinite loop* is one that would loop forever. (FYI, in a Python shell ctrl-c (^c) can be used to kill the running program.) Most infinite loops are caused by programmer error, but sometimes they are intentional. The following “*sentinel-controlled*” code uses an infinite loop and a *break* statement that immediately causes control to exit the loop.

```
total = 0
counter = 0
while True:      # an infinite loop
    score = eval(input("Enter a score (or negative value to exit): "))
    if score < 0:
        break
    total += score
    counter += 1
print("Average is", total/counter)
```

Strings: Strings in Python are sequential collections of only characters. Strings are immutable (i.e., cannot be changed), so new strings are generated by string operations. Operations on strings (or any sequence collection) include:

Operation	Operator	Explanation	Example	Result of Example
			myString = "Hello!!!" aString = "cat"	
Indexing	[<index>]	Access the element specified by the index	myString[1]	'e'
Slicing	[:]	Extract a part of the string	myString[1:5]	'ello'
Concatenation	+	Combine strings together	myString + aString	'Hello!!!cat'
Repetition	*	Concatenate a repeated number of times	aString * 3	'catcatcat'
Membership	in	Ask whether a substring is in a string	'ell' in myString	True
Length	len(string)	How many items are in the string?	len(myString)	8

Indexing of strings starts with 0 on the left end, and -1 on the right end:

```

1111
01234567890123
cheer = 'GO Panthers!!!'
-4-3-2-1
```

Omitted indexes in a slice means “from the end.” For example, cheer[:4] generates 'GO P'.

Omitted indexes in a slice means “from the end.” For example, cheer[-4:] generates 's!!!'.

String objects also have the following methods: (the `string` module can be imported to provide more operations.)

Method	Usage	Explanation
<code>center</code>	<code>myString.center(w)</code>	Returns a string with <code>myString</code> centered in a field of size <code>w</code>
<code>ljust</code>	<code>myString.ljust(w)</code>	Returns a string with <code>myString</code> left-justified in a field of size <code>w</code>
<code>rjust</code>	<code>myString.rjust(w)</code>	Returns a string with <code>myString</code> right-justified in a field of size <code>w</code>
<code>upper</code>	<code>myString.upper()</code>	Returns a string with <code>myString</code> in all upper-case characters
<code>lower</code>	<code>myString.lower()</code>	Returns a string with <code>myString</code> in all lower-case characters
<code>strip</code>	<code>myString.strip()</code>	Returns a string with leading and trailing whitespace (space, tab, new-line) chars. removed. An optional string parameter can be used to supply characters to strip instead of whitespace.
<code>count</code>	<code>myString.count(sub)</code>	Returns number of occurrences of <code>sub</code> in <code>myString</code> (Optional parameters: <code>myString.count(sub [, start [, end]])</code>)
<code>endswith</code>	<code>myString.endswith(sub)</code>	Returns True if <code>myString</code> ends with the substring <code>sub</code> ; otherwise it returns False
<code>startswith</code>	<code>myString.startswith(sub)</code>	Returns True if <code>myString</code> starts with the substring <code>sub</code> ; otherwise it returns False
<code>isdigit</code>	<code>myString.isdigit()</code>	Returns True if <code>myString</code> contains only digits; otherwise it returns False
<code>isalpha</code>	<code>myString.isalpha()</code>	Returns True if <code>myString</code> contains only letters; otherwise it returns False
<code>split</code>	<code>myString.split()</code>	Returns a list of substrings of <code>myString</code> splits at whitespace characters. An optional string parameter can supply characters to split on.
<code>find</code>	<code>myString.find(sub)</code>	Returns the starting index of the first occurrence of <code>sub</code> . (Optional parameters: <code>myString.find(sub [, start [, end]])</code>)
<code>replace</code>	<code>myString.replace(old,new)</code>	Returns a string with all occurrences of substring <code>old</code> replaced by substring <code>new</code> . An additional integer parameter can specify the number of replacements to perform, e.g., <code>myString.replace(old,new, 3)</code>

Lists: A Python list is also a sequence collection, but a list can contain items of any type (e.g., character, strings, integers, floats, other lists, etc.), and lists are mutable. Lists are represented by comma-separated values enclosed in square brackets (`'[', ']'`). Operations on lists (**or any sequence collection**, e.g., strings) include:

Operation	Operator	Explanation	Example <code>myList=[5,6,7,8]</code> <code>ListB=[8,9]</code>	Result of Example
Indexing	<code>[<index>]</code>	Access the element specified by the index	<code>myList[2]</code>	7
Slicing	<code>[:]</code>	Extract a part of the list	<code>myList[1:3]</code>	<code>[6, 7]</code>
Concatenation	<code>+</code>	Combine lists together	<code>myList + ListB</code>	<code>[5, 6, 7, 8, 8, 9]</code>
Repetition	<code>*</code>	Concatenate a repeated number of times	<code>ListB * 3</code>	<code>[8, 9, 8, 9, 8, 9]</code>
Membership	<code>in</code>	Ask whether an item is in a list	<code>3 in myList</code>	False
Length	<code>len(list)</code>	How many items are in the list?	<code>len(myList)</code>	4

The following list methods are provided by Python:

Method	Usage	Explanation
append	<code>myList.append(item)</code>	Adds item to the end of myList
extend	<code>myList.extend(otherList)</code>	Extends myList by adding all items in otherList to myList's end
insert	<code>myList.insert(i, item)</code>	Insert item in myList at index i
pop	<code>myList.pop()</code>	Remove and return the last item in myList
pop(i)	<code>myList.pop(i)</code>	Remove and return the ith item in myList
del	<code>del myList[i]</code>	Deletes the item in the ith position of myList
remove	<code>myList.remove(item)</code>	Removes the first occurrence of item in myList
index	<code>myList.index(item)</code>	Returns the index of the first occurrence of item in myList
count	<code>myList.count(item)</code>	Returns the number of occurrences of item in myList
sort	<code>myList.sort()</code>	Modifies myList to be sorted
reverse	<code>myList.reverse()</code>	Modifies myList to be in reverse order

Tuples: A tuple is another sequence data type, so the sequence operations of indexing, slicing, concatenation, repetition, membership (in), and len() work on tuples too. Tuples are very similar to lists, i.e., comma-separated items enclosed in parentheses. The main difference is that **tuples are immutable** (cannot be modified).

Create two tuples as:

```
student1 = ('Bob', 123456, 'Jr', 3.12)
student2 = ('Sally', 654321, 'Fr', 0.0)
```

In addition to indexing, “fields” of a tuple can be *unpacked* using a single assignment statement as:

```
name, idnum, rank, gpa = student1
```

(NOTE: This allows multiple values to be returned from a function)

Dictionaries: A dictionary is an unordered set of key-value pairs (written as key:value). Keys must be unique and immutable (e.g., numerics, strings, tuples of immutable objects). Dictionaries are typically used to lookup the value corresponding to a specified key. Dictionaries can be written as comma-separated key:value pairs enclosed in curly braces. For example,

```
phoneNumbers = {'fienup':35918, 'gray':35917, 'east':32939, 'drake':35811, 'schafer':32187}
```

Access to individual key:value pairs looks syntactically like a sequence lookup using a key instead of an index. For example, `phoneNumbers['east']` returns 32939, and a new key:value pair can be added by `phoneNumbers['wallingford'] = 35919`. Additional, methods on dictionaries are:

Method	Usage	Explanation
keys	<code>myDictionary.keys()</code>	Returns keys in an iterable <code>dict_keys</code> object
values	<code>myDictionary.values()</code>	Returns values in an iterable <code>dict_values</code> object
items	<code>myDictionary.items()</code>	Returns key:value tuples in an iterable <code>dict_items</code> object
get	<code>myDictionary.get(myKey)</code>	Returns the value associated with myKey; otherwise <i>None</i>
get	<code>myDictionary.get(myKey, alt)</code>	Returns the value associated with myKey; otherwise alt
in	<code>myKey in myDictionary</code>	Returns True if myKey is in myDictionary; otherwise False
del	<code>del myDictionary[myKey]</code>	Deletes the key:value pair whose key is myKey

Functions:

A *function* is a procedural abstract, i.e., a named body of code that performs some task when it is called/invoked. Often a function will have one or more parameter that allows it to perform a more general (variable) task. For example, the cube function below can be called with any numeric value with the corresponding cube of that number being returned.

```
# Function to calculate the cube of a number
def cube(num):
    num_squared = num * num
    return num_squared * num

# call the function
value = 2
print('The value', value, 'raised to the power 3 is', cube(value))
print('The value 3 raised to the power 3 is', cube(3))
```

Terminology:

- a *formal parameter* is the name of the variable used in the function definition. It receives a value when the function is called. In the function `cube`, `num` is the formal parameter. Formal parameters are only known inside of the function definition. The section of a program where a variable is known is called its *scope*, so the scope of a formal parameter (and other *local variable* defined in the function such as `num_squared`) is limited to the function in which it is defined.
- an *actual parameter/argument* is the value used in the function call that is sent to the function. In the call to function `cube`, the variable `value` supplies the actual parameter value of 2.
- a *global variable* is created outside all functions and is known throughout the whole program file, e.g. `value`.

It is helpful to understand the “rules of the game” when a function is called. Memory is used to store the current program and the data associated with it. The memory used to store the data is divided as shown below.

- Global memory is used to store the global variables (and constants).
- The *heap* is used to store dynamically allocated objects as the program runs, e.g. lists and objects
- The *run-time stack* is used to store *call-frames* (or *activation records*) that get *pushed* on the stack when a function is called, and *popped* off the stack when a function returns.

When a function is called the section of code doing the calling is temporarily suspended, and a new call-frames gets pushed on top of the stack before execution of the function body. The call-frame contains the following information about the function being called:

- the *return address* -- the spot in code where the call to the function occurred. This is needed so execution (control) can return there when the end of the function is reached or a `return` statement executes.
- room to store the formal parameters used by the function. In Python, parameters are *passed-by-value* which means that the value of each actual parameter in the function call is assigned to the corresponding formal parameter in the function definition before the function starts executing. However, the memory location for actual parameters for strings, lists, dictionaries, tuples, atomic objects contain only *references* to the heap
- room to store the local variables defined in the function (these are probably references to objects in the heap)

When a function returns, execution resumes at the function call (which is specified by the return address). A function typically sends back a value to the call by specifying an expression after `return` in the return statement. In Python if no expression is specified returned, then the special object `None` is returned.

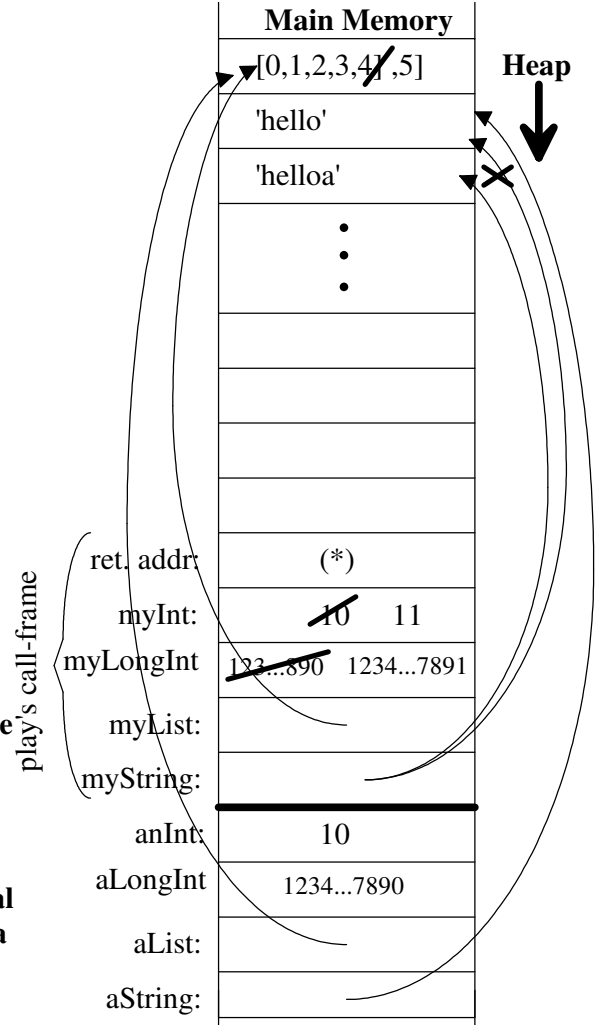

```
def play(myInt, myLongInt, myList, myString):
    print('START OF play Function')
    print('myInt=',myInt,'myLongInt=',myLongInt)
    print('myList=',myList,'myString=',myString)
    myInt += 1
    myLongInt += 1
    myList.append(1)
    myString += 'a'
    print('END OF play Function')
    print('myInt=',myInt,'myLongInt=',myLongInt)
    print('myList=',myList,'myString=',myString)
    return
```

```
anInt = 10
aLongInt = 123456789012345678901234567890L
aList = range(5)
aString = 'hello'
print('BEFORE CALL')
print('anInt=',anInt,'aLongInt=',aLongInt)
print('aList=',aList,'aString=',aString)
play(anInt, aLongInt, aList, aString)
print('AFTER CALL') (*)
print('anInt=',anInt,'aLongInt=',aLongInt)
print('aList=',aList,'aString=',aString)
```

Trace up to here

Run-time Stack

Global Data

Output of complete program:

```
>>>
BEFORE CALL
anInt= 10 aLongInt= 123456789012345678901234567890
aList= [0, 1, 2, 3, 4] aString= hello
START OF play Function
myInt= 10 myLongInt= 123456789012345678901234567890
myList= [0, 1, 2, 3, 4] myString= hello
END OF play Function
myInt= 11 myLongInt= 123456789012345678901234567891
myList= [0, 1, 2, 3, 4, 1] myString= helloa
AFTER CALL
anInt= 10 aLongInt= 123456789012345678901234567890
aList= [0, 1, 2, 3, 4, 1] aString= hello
>>>
```

NOTES:

- `aList` passes a copy of **its reference to** the list as the initial value of the formal parameter `myList`, so **both refer to the single list**. In `play` when `myList.append(1)` executes, the single list is changed. Thus, when `play` terminates, `aList` still reflect this change.
- `aString` passes a copy of its reference to the string ('hello') as the initial value of the formal parameter `myString`. Since strings are immutable (cannot be changed) in Python, executing `myString += 'a'` cause a whole new string 'helloa' to be recreated in memory with `myString` referencing it. `aString` still refers to the string 'hello'.
- the `int` objects should actually be stored in the heap like the string objects since `int`'s are immutable .

Text Files: Below is a summary of the important text-file operations in Python.

File Operations in Python		
General syntax	Example	Description
open(filename) open(filename, mode)	f = open('data.txt', 'w')	Modes: 'r' read only; 'w' write only; 'a' append; 'r+' both reading and writing. Default mode is 'r'
f.close()	f.close()	Close the file to free up system resources.
loop over the file object	for line in f: print (line)	Memory efficient, fast and simple code to loop over each line in the file.
f.readline()	nextLine = f.readline()	Returns the next line from the file. The newline ('\n') character is left at the end of the string.
f.write(string)	f.write('cats and dogs\n')	Writes the string to the file.
f.read()	all = f.read()	Returns the whole file as a single string.
f.read(size)	chunk = f.read(100)	Returns a string of at most 100 (size) bytes. If the file has been completely read, an empty string is returned.
f.readlines()	allLines = f.readlines()	Returns a list containing all the lines of the file.
f.readlines(size)	someLines = f.readlines(5000)	Returns the next 5000 bytes of line. Only complete lines will be returned.

Below is a summary of the important file-system functions from the `os` module in Python.

os Module File-system Functions	
General syntax	Description
getcwd()	Returns the complete path of the current working directory
chdir(path)	Changes the current working directory to path
listdir(path)	Returns a list of the names in directory named path
makedirs(path)	Creates a new directory named path and places it in the current working directory
rmdir(path)	Removes the directory named path from the current working directory
remove(path)	Removes the file named path from the current working directory
rename(old, new)	Renames the file or directory named old to new

os.path Module File-system Functions	
General syntax	Description
exists(path)	Returns True if path exists and False otherwise
isdir(path)	Returns True if path is a directory and False otherwise
isfile(path)	Returns True if path is a file and False otherwise
getsize(path)	Returns the size in bytes of the object named path

Classes: A *class* definition is like a blueprint (receipt) for each of the objects of that class

- A class specifies a set of data attributes and methods for the objects of that class
- The values of the data attributes of a given object make up its state
- The behavior of an object depends on its current state and on the methods that manipulate this state
- The set of a class's methods is called its *interface*

The general syntax of class definition is:

```
class MyClass [ ( superClass1 [, superClass2 ]* ) ]:
    '''Document comment which becomes the __doc__ attribute for the class'''
    def __init__(self, [param [, param]*]):
        '''Document comment for constructor method with self be referencing to the object itself'''
        #__init__body

        # defs of other class methods and assignments to class attributes

# end class MyClass
```

```
"""
File: simple_die.py
Description: This module defines a six-sided Die class.
"""

from random import randint

class Die(object):
    """This class represents a six-sided die."""

    def __init__(self):
        """The initial face of the die."""
        self._currentRoll = randint(1, 6)

    def roll(self):
        """Resets the die's value to a random number
        between 1 and 6."""
        self._currentRoll = randint(1, 6)

    def getRoll(self):
        """Returns the face value of the die."""
        return self._currentRoll

    def __str__(self):
        """Returns the string representation of the die."""
        return str(self._currentRoll)
```

Consider the following script to test the Die class and its associated output:

```
# testDie.py - script to test Die class
from simple_die import Die

die1 = Die()
die2 = Die()
print('die1 =', die1)      #calls __str__
print('die2 =', die2)
print()
print('die1.getRoll() = ', die1.getRoll())
print('die2.getRoll() = ', die2.getRoll())
die1.roll()
print('die1.getRoll() = ', die1.getRoll())
print('str(die1): ' + str(die1))
print('die1 + die2:', die1.getRoll() + die2.getRoll())
```

```
>>>
die1 = 2
die2 = 5

die1.getRoll() = 2
die2.getRoll() = 5
die1.getRoll() = 3
str(die1): 3
die1 + die2: 8
>>>
```

Classes in Python have the following characteristics:

- all class attributes (data attributes and methods) are *public* by default, unless your identifier starts with a single underscore, e.g, `self._currentRoll`
- all data types are objects, so they can be used as inherited base classes
- **objects are passed by reference when used as parameters to functions**
- all classes have a set of standard methods provided, but may not work properly (`__str__`, `__doc__`, etc.)
- most built-in operators (+, -, *, <, >, ==, etc.) can be redefined for a class. This makes programming with objects a lot more intuitive. For example suppose we have two Die objects: `die1` & `die2`, and we want to add up their combined rolls. We could use *accessor methods* to do this:

```
diceTotal = die1.getRoll() + die2.getRoll()
```

Here, the `getRoll` method returns an integer (type `int`), so the '+' operator being used above is the one for ints. But, it might be nice to “overload” the + operator by defining an `__add__` method as part of the Die class, so the programmer could add dice directly as in:

```
diceTotal = die1 + die2
```

The three most important features of *Object-Oriented Programming* (OOP) to simplify programs and make them maintainable are:

1. *encapsulation* - restricts access to an object's data to access only by its methods
 - ⇒ helps to prevent indiscriminant changes that might cause an invalid object state (e.g., 6-side die with a roll of 8)
2. *inheritance* - allows one class (the *subclass*) to pickup data attributes and methods of other class(es) (the *parents*)
 - ⇒ helps code reuse since the subclass can extend its parent class(es) by adding addition data attributes and/or methods, or overriding (through polymorphism) a parent's methods
3. *polymorphism* - allows methods in several different classes to have the same names, but be tailored for each class
 - ⇒ helps reduce the need to learn new names for standard operations (or invent strange names to make them unique)

Consider using inheritance to extend the Die class to a generalized AdvancedDie class that can have any number of sides. The interface for the AdvancedDie class are:

Detail Descriptions of the AdvancedDie Class Methods		
Method	Example Usage	Description
<code>__init__</code>	<code>myDie = AdvancedDie(8)</code>	Constructs a die with a specified number of sides and randomly rolls it (Default of 6 sides if no argument supplied)
<code>getRoll</code>	<code>myDie.getRoll()</code>	Returns the current roll of the die (inherited from Die class)
<code>getSides</code>	<code>myDie.getSides()</code>	Returns the number of sides on the die (did not exist in Die class)
<code>roll</code>	<code>myDie.roll()</code>	Rerolls the die randomly (By overriding the <code>roll</code> method of Die, an AdvancedDie can generate a value based on its # of sides)
<code>__eq__</code>	<code>if myDie == otherDie:</code>	Allows <code>==</code> operations to work correctly for AdvancedDie objects.
<code>__lt__</code>	<code>if myDie < otherDie:</code>	Allows <code><</code> operations to work correctly for AdvancedDie objects.
<code>__gt__</code>	<code>if myDie > otherDie:</code>	Allows <code>></code> operations to work correctly for AdvancedDie objects.
<code>__add__</code>	<code>sum = myDie + otherDie</code>	Allows the direct addition of AdvancedDie objects, and returns the integer sum of their current roll values.
<code>__str__</code>	Directly as: <code>myDie.__str__()</code> <code>str(myDie)</code> or indirectly as: <code>print myDie</code>	Returns a string representation for the AdvancedDie. By overriding the <code>__str__</code> method of the Die class, so the “print” statement will work correctly with an AdvancedDie.

Consider the following script and associated output:

```
# testAdvancedDie.py - script to test
AdvancedDie class
from advanced_die import AdvancedDie

die1 = AdvancedDie(100)
die2 = AdvancedDie(100)
die3 = AdvancedDie()

print( 'die1 =', die1 )      #calls __str__
print( 'die2 =', die2 )
print( 'die3 =', die3 )

print( 'die1.getRoll() = ', die1.getRoll() )
print( 'die1.getSides() = ', die1.getSides() )
die1.roll()
print( 'die1.getRoll() = ', die1.getRoll() )
print( 'die2.getRoll() = ', die2.getRoll() )
print( 'die1 == die2:', die1==die2 )
print( 'die1 < die2:', die1<die2 )
print( 'die1 > die2:', die1>die2 )
print( 'die1 != die2:', die1!=die2 )
print( 'str(die1): ' + str(die1) )
print( 'die1 + die2:', die1 + die2 )

help(AdvancedDie)
```

```
die1 = Number of Sides=100 Roll=32
die2 = Number of Sides=100 Roll=76
die3 = Number of Sides=6 Roll=5
die1.getRoll() = 32
die1.getSides() = 100

die1.getRoll() = 70
die2.getRoll() = 76
die1 == die2: False
die1 < die2: True
die1 > die2: False
die1 != die2: True
str(die1): Number of Sides=100 Roll=70
die1 + die2: 146
Help on class AdvancedDie in module
advanced_die:

class AdvancedDie(simple_die.Die)
