1 Part I - Programmers Guide

1.1 Introduction

The MDH (Multi-Dimensional and Hierarchical) Database Toolkit is a Linux-based, open sourced, toolkit of portable software that supports fast, flexible, multi-dimensional and hierarchical storage, retrieval and manipulation of information in data bases ranging in size up to 256 terabytes. The package is written in C and C++ and is available under the GNU GPL/LGPL licenses in source code form. The distribution kit contains demonstration implementations of network-capable, interactive text and sequence retrieval tools that function with very large genomic data bases and illustrate the toolkit’s capability to manipulate massive data sets of genomic information.

The toolkit is distributed as part of the Mumps Compiler Versions exist for Linux, Cygwin, the DJGPP port of the GCC compiler for Windows XP and the command line version of the MicroSoft Visual C++ Compiler

The toolkit is a solution to the problem of manipulating very large, character string indexed, multi-dimensional, sparse matrices. It is based on Mumps (also referred to as M), a general purpose programming language that originated in the mid 60’s at the Massachusetts General Hospital. The toolkit supports access to the PostgreSQL relational data base server, the Perl Compatible Regular Expression Library, the Berkeley Data Base, and the Glade GUI builder as well as server-side development of interactive web pages.

The principal database feature in this project is the global array which permits direct, efficient manipulation of multi-dimensional arrays of effectively unlimited size. A global array is a persistent, sparse, undeclared, multi-dimensional, string indexed data disk based structure. A global array may appear anywhere an ordinary array reference is permitted and data may be stored at leaf nodes as well as intermediate nodes in the data base array. The number of subscripts in an array reference is limited only by the total length of the array reference with all subscripts expanded to their string values. The toolkit includes several functions to traverse the data base and manipulate the arrays.

The toolkit makes the data base and function set available as C++ classes and also permits execution of legacy Mumps scripts. To use the toolkit, you install the MDH and Mumps distribution kit and related code.

2 Creating Global Arrays

The class, function and macro libraries primarily operate on global arrays. Global arrays are undimensioned, string indexed, disk resident data structures whose size is limited only by available disk space. They can be viewed either as multi-dimensional sparse matrices or as tree structured hierarchies. Global arrays are a C++ class and must be declared or instantiated in your C++ program as an instance of the global. For example, to create the global named “gbl”, do the following:

```c
#include <mumps/libmumpspp.h>
global gbl("gbl");
```

The instantiation consists of two parts: the name of the global array object and the name of the global array on disk associated with this object. In the above example, these are both “gbl”. Note that the disk name of the global is enclosed in a parenthesized character string expression following the object name. The name in the expression need not (but usually does) match the name of the object. The name given in the parenthesized character string is the disk name of the global array. The global array object is associated with the disk name when the object is created. When the object is destroyed, the disk based global array persists.

Note: programs that use global arrays MUST close the array file system with the GlobalClose; command before exiting. Failure to do so may corrupt the file system.

Global objects may be created through declarations as shown above or dynamically:

```c
global *gptr;
```

```
gptr = new global ("gbl_name");
(*gptr)("1","2","3") = "test";
```

which is equivalent to:

```
global g("gbl_name");
g("1","2","3") = "test";
```

The `#include <mumpsc/libmpscpp.h>` statement brings in the necessary header files for your C++ program. These include, in addition to the header files necessary to access the toolkit, the standard system libraries:

```
#include <iostream>
#include <iomanip>
#include <string>
#include <string.h>
#include <math.h>
#include <stdlib.h>
```

These are referenced at the beginning of `libmpscpp.h.in` and you may modify them if your system uses different naming conventions.

Each `global` declaration creates a global array name (`gbl`) to be an object or instance of the `global` class. Each global array you use must be first declared to be an object of the `global` class. Global names can be any valid C/C++ variable name.

A global array will typically have one or more subscripts as discussed below. These will be of type `mstring`, or a null terminated array of `char`. Subscripts of global arrays must evaluate to a printable characters in the range of decimal 32 (space) to, but not including, tilde (~).

Note:

- No data types other than `mstring`, or null terminated array of `char` (i.e., `char *`) may be used as subscripts. Numeric data types (int, short, long, float, double, etc.) may not be used as global array subscripts.

- Also, in any given global array reference, all the indices must be of the same data type (`mstring` or `char *`)

`mstring` is a data type (class) whose behavior is similar to the basic typeless string data type in Mumps. Objects of `mstring` are stored internally as strings but may contain text, integers and floating point values. Addition, multiplication, subtraction, division, modulo, and concatenation may be performed directly on `mstring` objects (see details below). Many of the following examples use `mstring` objects.

### 2.1 Structure of Global Arrays

Global arrays may be viewed either as multi-dimensional matrices or as tree structured hierarchies. As matrices, data may be stored not only at fully subscripted matrix elements but also at other levels. For example, given a three dimensional matrix `mat1`, you could initialize it as follows:

```
#include <mumpsc /libmpscpp.h>

global mat1("mat1");

int main() {
    mstring i,j,k;
    for (i=0; i<100; i++)
        for (j=0; j<100; j++)
            for (k=0; k<100; k++) {
                mat1(i,j,k)=0;
```
Alternatively, the above can be performed with int but the numeric indices must be converted to mstring before use:

```c
#include <mumpsc /libmpscpp.h>

global mat1("mat1");

int main() {
    int i,j,k;
    for (i=0; i<100; i++)
        for (j=0; j<100; j++)
            for (k=0; k<100; k++) {
                mat1(mcvt(i),mcvt(j),mcvt(k))=0;
            }

    GlobalClose;
    return 0;
}
```

In this example, all the elements of a three dimensional matrix of 100 rows, 100 columns and 100 planes are initialized to zero. The function mcvt() converts from int to mstring.

In the view expressed by the code above, the matrix is a traditional three dimensional structure with data stored at each fully indexed position or node.

Unlike other programming languages, however, there are additional nodes of the matrix which could have been initialized such as indicated by the following example:

```c
#include <mumpsc /libmpscpp.h>

global mat1("mat1");

int main() {
    mstring i,j,k;
    for (i=0; i<100; i++) {
        mat1(i)=i;
        for (j=0; j<100; j++) {
            mat1(i,j)=j;
            for (k=0; k<100; k++) {
                mat1(i,j,k)=0;
            }
        }
    }

    return 0;
}
```

In effect, this means that mat1 can also be a single dimensional vector, a two dimensional matrix and a three dimensional matrix simultaneously.

Furthermore, not all elements of a matrix need exist. That is, the matrix can be sparse. For example:

```c
#include <mumpsc/libmpscpp.h>
```
In the above, only index values 0, 10, 20, 30, 40, 50, 60, 70, 80, and 90 are used to create each of the dimensions of the array and only those elements of the matrix are created. The omitted elements do not exist.

For example, if you are running a drug protocol on a number of patients and are dosing with medications M1, M2, M3, ... on patients P1, P2, P3, ... and collecting observations on days D1, D2, D3, ... you could create a three dimensional matrix named `protocol` in which each plane consisted of the observations for each patient on each medication for a given day:

<table>
<thead>
<tr>
<th>D1</th>
<th>D2</th>
<th>D3</th>
<th>D4</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>M1</td>
<td>M2</td>
<td>M3</td>
</tr>
<tr>
<td>P1</td>
<td></td>
<td>P1</td>
<td>P1</td>
</tr>
<tr>
<td>P2</td>
<td></td>
<td>P2</td>
<td>P2</td>
</tr>
<tr>
<td>P3</td>
<td></td>
<td>P3</td>
<td>P3</td>
</tr>
</tbody>
</table>

You could refer to patient P1, medication M2 on day D4 with the reference:

`protocol("P1","M2","D4")="X";`

Alternatively, you can view the same data base as a tree structure with patient id at the root, followed by medication, followed by day of study:
Note that at each node in the tree, a data box may appear containing information about the node. Addressing a node is accomplished by giving its path description such as:

\[ \text{protocol("P2","M2",D2)} \]

### 3 Compiling Programs

To compile programs written in C++ that use the MDH (multi-Dimensional and Hierarchical) library, use the command:

\[ \text{mumps c myprog.cpp} \]

This will invoke the \texttt{g++} compiler and make available the necessary libraries. The result will be a program named \texttt{myprog} which is executable. The \texttt{cgi} extension is used as the default because very often these programs may be used in connection with web servers. You may rename the program as you see fit, however. The script \texttt{mumps c} is part of the Mumps Compiler which must be installed prior to using the toolkit.

### 4 Accessing Global Arrays

Note: prior to exiting a program that accessed globals arrays, you must execute a \texttt{GlobalClose} macro to shut down the global array facility. This flushes the system buffers to disk and insures that the file system if properly closed. Failure to do this will result in data base errors. This appears in your program as:

\[ \text{GlobalClose;} \]

You may assign global array elements to variables of type \texttt{mstring} using the assignment operator(=).

You may assign values of type \texttt{int}, \texttt{float}, \texttt{double}, \texttt{mstring}, \texttt{string} and \texttt{char *} to global array elements using the assignment operator (=).

When global array references are passed to function, no more than one instance of the same \texttt{global} object should be used in the argument list. Each \texttt{global} object maintains a private static string which contains the most recent value fetched from the data base. When a \texttt{global} object is passed to a function, its this string value is effectively passed. This means that, in a function reference where two references to the same \texttt{global} object are passed, even though they have
differing indices, the value passed will be the value for the second instance of the `global`. This restriction only applies where there are two or more instances of the same `global`.

If you use a reference to a `global` without a parenthesized list following the name of the `global`, the reference will be to the most recent referenced `global`. Effectively, this is similar to the “naked indicator” from Mumps.

### 4.1 Global Array Indices

Internally, the indices of global arrays are always stored as character strings. If you initialize a global array with a loop, you must insure that the indices are represented as either values of type `mstring` or null terminated arrays of type `char`. Indices to globals may be either `char*` or `mstring` but MUST all be of the same type (i.e. all `char*` or all `mstring`). For example:

```plaintext
mstring A,B,C;
for (A=0; A<1000; A++)
  for (B=0; B<1000; B++)
    for (C=0; C<1000; C++) {
      array1(A,B,C) = "0"
    }
```

The above initializes an array of 1 billion elements to zero.

### 4.2 Navigating Globals

There are several built-in functions used to navigate the globals. The two most important are the `Data()` function and the `Order()` function. The `Data()` function tells you if a node exists and if it has descendants and the `Order()` function gives you the next higher (or lower) index at a given level in the global array tree.

The `Data()` function returns an integer which indicates whether the global array node is defined:

1. 0 if the global array node is undefined;
2. 1 if it is defined and has no descendants;
3. 10 if it is defined but has no value stored at the node (but does have descendants);
4. 11 it is defined and has descendants.

A global is defined if data has been stored at it. A "10" is returned for a node at which nothing has been stored but the node has descendants. For example, assuming the global array has only the contents created in the example below:

```plaintext
global array1("array1");
int result;
array1("1","11") = "foo"
array1("1","11","21") = "bar"

result = array1("1").Data() ; // yields 10
result = array1("1","11").Data(); // yields 11
result = array1("1","11","21").Data(); // yields 1
```

The other major navigation function is the `Order()` function. This gives you, for a given global array index, the next ascending or descending value for the last index. If the parameter to `Order()` is 1 or missing, the next ascending index is returned. If the parameter is -1, the next descending index is returned. To get the first (or last if the parameter is -1) value of an index, start with a null (empty) string. For example:

```plaintext
mstring x, null;
global array1("array1");

array1("100") = "a"; // initialize the array with three entries
```
array1("200") = "b";
array1("300") = "c";

null = "";

x = array1(null).Order();   // get the first value of the first index: 100
x = array1(x).Order();     // get the second value of the first index: 200
x = array1(x).Order();     // get the third value of the first index: 300
x = array1(x).Order();     // no more indices - returns empty string
x = array1(null).Order(-1);  // get the last value of the first index: 300
x = array1(x).Order(-1);   // get the second value of the first index: 200
x = array1(x).Order(-1);   // get the first value of the first index: 100
x = array1(x).Order(-1);   // no more indices - returns empty string

for ( x = array1(null).Order(); x != null; x = array1(x).Order())
    cout x << endl;  // writes 100 200 300 on separate lines

for ( x = array1(null).Order(-1); x != null; x = array1(x).Order(-1))
    cout x << endl;  // writes 300 200 100 on separate lines

for ( x = 10; x < 100; x = x + 10) array1("200", x) = x;

for ( x = array1("200", null).Order(); x != null; x = array1("200", x).Order())
    cout x << endl;  // writes 10 20 30 ... 90 on separate lines

Each call to Order() gives the next value of the last index. The numeric parameter indicates if the
direction is ascending (1) or descending (-1). If omitted, 1 is assumed. To get the first index, the
empty string is supplied and the function returns the first index of the global array. For subsequent
calls, it returns the next ascendant index value until there are no more indices. Then it returns the
empty string.

In the following example, we build a global array vector from an input file consisting of keywords
with one keyword per line, keep a count of each time the keyword is used, and, at the end, print an
alphabetized list of the keywords followed by the number of times each occurs, do the following:

#include <mumpsc/libmpscpp.h>
global key("key");

int main() {

        mstring word, null;
        long i;

        null = "";

        while (1) {
            if ( ! word.ReadLine(cin)) break;
            if (key(word).Data())  // is word in vector?
                key(word)++;  // yes, increment count
else key(word) = 1; // not in vector - add

word = null;

while ((word = key(word).Order(1)) != null) // next word
    cout << word << " " << key(word) << endl; // print word and count
return EXIT_SUCCESS;

In the above, each line is read into the variable word until the end of file is reached. Each word is tested with the Data() function of the global array to determine if word exists in the key vector. The Data() returns zero if the element does not exist, non-zero if it does. In the case where the word is in the key global array vector, the value stored in the vector for the word is extracted into the variable i, incremented and stored back into the vector. If the word does not exist in the vector, it is added and its initial count is set to one.

When all the words have been read and stored into the vector, the program sequences through the word entries and prints the words and the total number of times each one was present in the input file. Since global arrays are stored in ascending key order, the display of words will be alphabetic.

Similarly, given a global array of patient lab data organized hierarchically first by patient id, then by lab test, then by date, we can print a table of patient id's, labs, dates and results with the following:

```c++
#include <mumpsc/libmpscpp.h>

global Labs("labs");

int main() {

mstring null, ptid, lab_test, date, rslt;
null = "";

// create dummy example data base

Labs("1000","hct","July 12, 2003")="45";
Labs("1000","hct","July 13, 2003")="46";
Labs("1000","hct","July 14, 2003")="47";
Labs("1000","hct","July 15, 2003")="48";
Labs("1000","hgb","July 12, 2003")="15";
Labs("1000","hgb","July 15, 2003")="14";
Labs("1001","hct","July 12, 2003")="35";
Labs("1001","hct","July 13, 2003")="36";
Labs("1001","hct","July 14, 2003")="37";
Labs("1001","hct","July 15, 2003")="38";
Labs("1001","hgb","July 13, 2003")="15";
Labs("1001","hgb","July 14, 2003")="15";
Labs("1002","hct","Sept 12, 2003")="35";
Labs("1002","hct","Sept 13, 2003")="36";
Labs("1002","hct","Sept 14, 2003")="37";
Labs("1002","hct","Sept 15, 2003")="38";
Labs("1002","hgb","Sept 13, 2003")="15";
Labs("1002","hgb","Sept 14, 2003")="15";
```
ptid = null;

while ( (ptid = Labs(ptid).Order(1)) != null) {
    lab_test = null;
    while ( (lab_test = Labs(ptid,lab_test).Order(1)) != null) {
        date = null;
        while ( (date = Labs(ptid,lab_test,date).Order(1)) != null) {
            cout << ptid << " " << lab_test << " " << date ;
            cout << " " << Labs(ptid,lab_test,date) << endl;
        }
    }
    GlobalClose;
}

return 1;

The above begins with an empty string for patient id \textit{ptid}. This is used at the outer loop level to cycle through all the patient ids. At the first nexted loop, the program cycles through all the lab test names (\textit{lab_test}) then at the innermost level, it cycles through all the dates (\textit{date}). The resulting table is of the form:

<table>
<thead>
<tr>
<th>Patient ID</th>
<th>Test Type</th>
<th>Date</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>1000</td>
<td>hct</td>
<td>July 12, 2003</td>
<td>45</td>
</tr>
<tr>
<td>1000</td>
<td>hct</td>
<td>July 13, 2003</td>
<td>46</td>
</tr>
<tr>
<td>1000</td>
<td>hct</td>
<td>July 14, 2003</td>
<td>47</td>
</tr>
<tr>
<td>1000</td>
<td>hct</td>
<td>July 15, 2003</td>
<td>48</td>
</tr>
<tr>
<td>1000</td>
<td>hgb</td>
<td>July 12, 2003</td>
<td>15</td>
</tr>
<tr>
<td>1000</td>
<td>hgb</td>
<td>July 15, 2003</td>
<td>14</td>
</tr>
<tr>
<td>1001</td>
<td>hct</td>
<td>July 12, 2003</td>
<td>35</td>
</tr>
<tr>
<td>1001</td>
<td>hct</td>
<td>July 13, 2003</td>
<td>36</td>
</tr>
<tr>
<td>1001</td>
<td>hct</td>
<td>July 14, 2003</td>
<td>37</td>
</tr>
<tr>
<td>1001</td>
<td>hct</td>
<td>July 15, 2003</td>
<td>38</td>
</tr>
<tr>
<td>1001</td>
<td>hgb</td>
<td>July 13, 2003</td>
<td>15</td>
</tr>
<tr>
<td>1001</td>
<td>hgb</td>
<td>July 14, 2003</td>
<td>15</td>
</tr>
</tbody>
</table>

4.3 Locking the Data Base

There are several functions for locking portions of the data base. Following legacy convention, a lock does not prevent access to an element but merely flags the element as locked. Locking views a global array as a tree structure. If an element is locked, its descendants are locked. An attempt to lock a locked element of an element that has a locked parent or a locked descendant will fail. The primary locking functions are \texttt{$lock()$, Lock()} and \texttt{UnLock():}

```c
    if ($lock(gbl(a,b,c)) cout << "locked" << endl;
    if (gbl(a,b,c).Lock()) cout << "locked" << endl;
    gbl(a,b,c).UnLock();
```

The \texttt{$lock() \text{ and Lock()}$} functions test to see if the node can be locked and locks it if possible. It returns \texttt{true} (1) if successful and false (0) otherwise ($test$ is set accordingly). A node can be locked if
it itself is not locked, if it has no descendants that are locked and if it is not the descendant of a locked node. The \texttt{UnLock()} function releases a lock on a node.

Additionally, there are functions to release all locks for the current process and all locks for all processes:

\begin{alltt}
CleanLocks(); // release all locks for this process only
CleanAllLocks(); // release all locks for all processes
\end{alltt}

\section*{5 Invoking the Mumps Interpreter}

The full facilities of the Mumps interpreter can be invoked from C++ programs. The interpreter reads, parses and executes commands presented to it at run time. It may also read and execute text files containing Mumps programs. The interpreter is invoked by means of the \texttt{Xecute()} macro and \texttt{xecute()} functions:

\begin{alltt}
int Xecute("command")
int xecute(mstring command)
int xecute(string command)
int xecute(char * command)
\end{alltt}

These functions and macro invoke the Mumps interpreter and execute the text replacing "command". They return 1 of successful, 0 otherwise. With \texttt{Xecute()}, if the mumps command contains quotes or other special symbols, they will be automatically prefixed with backslashes (e.g., quote becomes \".

\begin{alltt}
Xecute("set i="test");
Xecute("fors i=${order(^a(i))} quit:i=" set sum=sum+^a(i)";
\end{alltt}

Details on the Mumps Language are contained in the file \texttt{compiler.html} in the \texttt{mumpsc/doc} subdirectory of the Mumps Compiler distribution. See also: \texttt{mtring::Eval()} for expression interpretation.

\section*{6 Writing Active Web Server Pages}

C++ programs can be written with the toolkit to be web server active pages. For example:

Web page HTML code:

\begin{alltt}
<html>
<title>Your title goes here</title>
<form method="get" action="quiz2.cgi">
<center>
Name:
<input type="text" name="name" size=40 value="">
<br>
</center>
Class:
<input type="Radio" name="class" value="freshman" > Freshman
<input type="Radio" name="class" value="sophmore" > Sophmore
<input type="Radio" name="class" value="junior" > Junior
<input type="Radio" name="class" value="senior" checked> Senior
<input type="Radio" name="class" value="grad" > Grad Student
<br>
Major:
<select name="major" size=1>
<option value="computer science" >computer science
<option value="mathematics" >Mathematics
</select>
</form>
</html>
\end{alltt}
A C++ program can accept data from the web page, store the data in global arrays and return a summary web page to the browser. When using "get" mode data transmission from HTML forms, the form names and data are concatenated into a string, delimited by ampersands, containing "name=value" tokens. These are passed in an environment variable named QUERY_STRING. The include file mumps/cgi.h contains code to extract data from QUERY_STRING and store the data in the runtime symbol table. The function SymGet() can be used to retrieve values from runtime symbol table.

```
#include <mumps /libmpscpp.h>

global T("T");

int main() {

mstring name;
    mstring class;
    mstring major;
    mstring hobby1;
    mstring hobby2;
    mstring hobby3;
    mstring hobby4;
    mstring hobby5;

#include <mumps /cgi.h>

cout << "Content-type: text/html " << endl << endl;

name = SymGet("name");
    class = SymGet("class");
    major = SymGet("major");
    hobby1 = SymGet("hobby1");
    hobby2 = SymGet("hobby2");
    hobby3 = SymGet("hobby3");
    hobby4 = SymGet("hobby4");
    hobby5 = SymGet("hobby5");
```
if (name == "") {
    cout << "Name not specified <br> ";
    cout << "" << endl; return EXIT_FAILURE; } T(name, mcvr("class")) =
class; T(name, mcvr("major")) = major; if (hobby1.Length() != 0) T(name,
mcvr("hobbies"), hobby1) = "; if (hobby2.Length() != 0) T(name,
mcvr("hobbies"), hobby2) = ""; if (hobby3.Length() != 0) T(name,
mcvr("hobbies"), hobby3) = ""; if (hobby4.Length() != 0) T(name,
mcvr("hobbies"), hobby4) = ""; if (hobby5.Length() != 0) T(name,
mcvr("hobbies"), hobby5) = ""; cout << "Thank you " << name << " for your
input ";
cout << "" << endl; return EXIT_SUCCESS; }

Note: you can test code by simulating input from a web browser with the following code:

```bash
#!/bin/bash
QUERY_STRING="abc=xyz&cde=123"
export QUERY_STRING
your_program.cgi
```

The "name=value" sets (delimited by ampersands) will be passed to the program. Note: web
server cgi protocol requires the value strings to be encoded (see EncodeHTML()).

## 7 Class mstring

The **mstring** class provides Mumps-like strings that can be used to write programs in C++ that
treat variables in a manner similar to that of Mumps. This means that **mstring** objects are essentially
strings on which arithmetic operations may be performed. The **mstring** includes overloads for many
operators as well as the following functions:

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>mstring Horolog()</td>
<td>Returns an <strong>mstring</strong> of the form &quot;x,y&quot; where x is the number of days since December 31, 1984 and y is the number of seconds since midnight.</td>
</tr>
<tr>
<td>mstring ScanAlnum(FILE *, int min=3, int max=25)</td>
<td>Returns the next token from the input file with all punctuation removed. Returns empty string on end of file. If min and/or max are provided, only words whose length are less than min and greater than max are discarded. The default values for these parameters are 3 and 25, respectively. Use stdin for file to scan standard input.</td>
</tr>
<tr>
<td>mstring ScanAlnum(istream, int min=3, int max=25)</td>
<td>Evaluates the mumps expression of the invoking mstring object and returns the result in an mstring. If an error occurs, an InterpreterException is thrown. The invoking mstring object may contain a valid mumps expression involving calling program mstring variables.</td>
</tr>
<tr>
<td>mstring mstring::Eval()</td>
<td>Replaces the string matching pattern with replacement. Returns 1 if successful, 01 if there was</td>
</tr>
<tr>
<td>Function</td>
<td>Description</td>
</tr>
<tr>
<td>-----------------------------------------------</td>
<td>-----------------------------------------------------------------------------</td>
</tr>
<tr>
<td>int mstring::decorate(mstring pattern,</td>
<td>Locates the pattern in the invoking mstring and inserts left immediately to the left of the string that matched the pattern and inserts right immediately to the right of the found pattern. Returns 1 if the pattern was found and the insertions were made, -1 if the pattern was not found, and less than -1 for other errors (see PCRE documentation concerning <code>pcre_exec()</code> return codes). Throws: PatternException().</td>
</tr>
<tr>
<td>mstring prefix,</td>
<td></td>
</tr>
<tr>
<td>mstring suffix)</td>
<td></td>
</tr>
<tr>
<td>int mstring::ends(mstring pattern)</td>
<td>Returns an integer giving the character position (relative to zero) immediately following the string that matched pattern. Returns -1 if the string did not match. Throws: PatternException.</td>
</tr>
<tr>
<td>int mstring::begins(mstring pattern)</td>
<td>Returns an integer which is the starting point in the string of pattern or -1 if the pattern is not found. Throws: PatternException if the pattern is in error.</td>
</tr>
<tr>
<td>bool mstring::ReadLine(FILE *)</td>
<td>The next line from the file designated by &quot;unit&quot; is read into the invoking object of mstring. Carriage-returns and line-feeds are removed. The maximum length line that can be read is STR_MAX - 1. Returns 'true' if the operation succeeded, 'false' otherwise or if end of file.</td>
</tr>
<tr>
<td>bool mstring::ReadLine(istream &amp;)</td>
<td></td>
</tr>
<tr>
<td>int mstring::Pattern(mstring &amp;)</td>
<td>Evaluates the invoking source string according to the pattern_string and returns 0 (does not match) or 1 (does match). Pattern_string rules are as as shown below but you must remember to place a backslash before quotes in the pattern string (as per usual C++ rules).</td>
</tr>
<tr>
<td>int mstring::Pattern(const char *)</td>
<td></td>
</tr>
<tr>
<td>mstring mstring::Justify(int,int=-1)</td>
<td>Justify() right justifies the invoking mstring in an mstring field whose length is given by the first argument. If the second argument is present and a positive integer, the invoking mstring is right justified in a field whose length is given by the first argument with &quot;precision&quot; decimal places. The two argument form imposes a numeric interpretation upon the first argument.</td>
</tr>
<tr>
<td>Function</td>
<td>Description</td>
</tr>
<tr>
<td>----------</td>
<td>-------------</td>
</tr>
<tr>
<td><code>int mstring::Length()</code></td>
<td>The function returns the string length of the invoking mstring.</td>
</tr>
<tr>
<td><code>int mstring::Length(mstring pattern_string)</code></td>
<td>Returns the numeric value of an ASCII character. If no &quot;start&quot; is specified, the numeric values of the first character of invoking mstring is used. If &quot;start&quot; is specified, the numeric value of &quot;start&quot;'th character of invoking is chosen. If the empty string is given, -1 is returned.</td>
</tr>
<tr>
<td><code>int mstring::Ascii()</code></td>
<td>Returns an mstring containing a substring substring of the first argument. The substring begins at the position noted by the second operand. If the third operand is omitted, the substring consists only of the &quot;start&quot; character of invoking source string. If the third argument is present, the substring begins at position &quot;start&quot; and ends at position &quot;end&quot;. If no argument is given, the function returns the first character of the string. If &quot;end&quot; specifies a position beyond the end of source string, the substring ends at the end of source string; String position counting begins at one (not zero).</td>
</tr>
<tr>
<td><code>mstring mstring::Extract(int=1, int=-1)</code></td>
<td>Find() searches the first argument for an occurrence of the second argument. If one is found, the value returned is one greater than the end position of the second argument in the first argument. If &quot;start&quot; is specified, the search begins at position &quot;start&quot; in argument 1. If the second argument is not found, the value returned is 0. String position counting begins at position one.</td>
</tr>
<tr>
<td><code>int mstring::Find(const char *, int=1)</code></td>
<td>Find() searches the first argument for an occurrence of the second argument. If one is found, the value returned is one greater than the end position of the second argument in the first argument. If &quot;start&quot; is specified, the search begins at position &quot;start&quot; in argument 1. If the second argument is not found, the value returned is 0. String position counting begins at position one.</td>
</tr>
<tr>
<td><code>mstring mstring::Piece(const char *, int, int=-1)</code></td>
<td>Find() searches the first argument for an occurrence of the second argument. If one is found, the value returned is one greater than the end position of the second argument in the first argument. If &quot;start&quot; is specified, the search begins at position &quot;start&quot; in argument 1. If the second argument is not found, the value returned is 0. String position counting begins at position one.</td>
</tr>
</tbody>
</table>
For example:

```cpp
#include <mumps /libmpscpp.cpp>

global x("x");

int main() {
    mstring a, b, c;
    a = "hello ";
    b = "world";
    cout << (a || b) << endl;  // concatenation
    // prints "hello world"
    for (a = 0; a < 10; a++)
        cout << a << endl;  // prints 0 thru 9
    for (a = 0; a < 10; a++)
        x(a) = a;  // sets global array elements
    a = "";
    while (1) {
        a = x(a).Order(1);
        if (a == "") break;
        cout << a << endl;  // prints 0 thru 9
    }
    cout << x(a).Data() << endl;  // prints 1
    c = "123 elm street";
    c = c + 1;
    cout << c << endl;  // prints 124

    return EXIT_SUCCESS;
}
```

Note: the code "(a || b)" in the cout expression is parenthesized. If not parenthesized, the C++ compiler precedence will result in an error since the precedence of << is greater than ||.

Objects of class `mstring` may:

1. Be assigned values from variables or constants of types `char *`, `string`, `global`, `mstring`, `float`, `int`, or `double`;

Examples:

```cpp
int main() {
    // example of assignment to mstring
    // mdH1.cpp
    mstring x;
    x = 10;  // cout << x << endl;
    x = 10.99;  // cout << x << endl;
    x = "test";  // cout << x << endl;
```
string a1="abcdef";
float  a2=99.9;
double a3=99.8;
int    a4=99;
short  a5=98;
char   a6[]="abcdef";
global a7("a7"); a7("1")=99;

x = a1; cout << x << endl;

x = a2; cout << x << endl;

x = a3; cout << x << endl;

x = a4; cout << x << endl;

x = a5; cout << x << endl;

x = a6; cout << x << endl;

x = a7("1"); cout << x << endl;

GlobalClose;

return EXIT_SUCCESS;

which writes:

10
10.99
test
abcdef
99.9
99.8
99
98
abcdef
99

#include &lt;mumpsc /libmpscpp.h&gt;

int main() {

// mdhT2.cpp - example mstring operators.

mstring x;
mstring y;
mstring z;

y = 1;
x = 10;

cout << "expect 11 " << x + 1 << endl;
cout << "expect 9 " << x - 1 << endl;
cout << "expect 20 " << x * 2 << endl;
cout << "expect 5 " << x / 2 << endl;
cout << "expect 1 " << x % 3 << endl;
cout << "expect 11 " << x + y << endl;

cout << "-----\n";
x = 10; x = x + 1;  cout << "expect 11 " << x << endl;
x = 10; x = x - 1;  cout << "expect 9 " << x << endl;
x = 10; x = x * 2;  cout << "expect 20 " << x << endl;
x = 10; x = x / 2;  cout << "expect 5 " << x << endl;
x = 10; x = x % 3;  cout << "expect 1 " << x << endl;
x = 10; x = x + y;  cout << "expect 11 " << x << endl;
x = 10; x = y + x;  cout << "expect 11 " << x << endl;

cout << "-----\n";

x = 10; x += 1;  cout << "expect 11 " << x << endl;
x = 10; x -= 1;  cout << "expect 9 " << x << endl;
x = 10; x *= 2;  cout << "expect 20 " << x << endl;
x = 10; x /= 2;  cout << "expect 5 " << x << endl;
x = 10; x %= 3;  cout << "expect 1 " << x << endl;

cout << "-----\n";

x = 10; x = 1 + x + y;  cout << "expect 12 " << x << endl;
x = 10; x = 1 - x + y;  cout << "expect 8 " << x << endl;
x = 10; x = 1 * x + y;  cout << "expect 11 " << x << endl;
x = 10; x = 1 / x + y;  cout << "expect 1.1 " << x << endl;

cout << "-----\n";

x = 10; x = 1 + ( x + y ); cout << "expect 12 " << x << endl;
x = 10; x = (x + y) + ( x + y ); cout << "expect 22 " << x << endl;

x = 10; cout << "expect 11 " << ++x ;
cout << " expect 11 " << x << endl;
x = 10; cout << "expect 10 " << x++ ;
cout << " expect 11 " << x << endl;
x = 10; cout << "expect 9 " << --x ;
cout << " expect 9 " << x << endl;
x = 10; cout << "expect 10 " << x--;
cout << " expect 9 " << x << endl;

cout << "-----\n";

x = 10; cout << "expect yes "; if ( x == 10 ) cout << "yes\n";
x = 10; cout << "expect yes "; if ( x >= 10 ) cout << "yes\n";
x = 10; cout << "expect yes "; if ( x < 10 ) cout << "yes\n";
x = 10; cout << "expect yes "; if ( x == 9 ) cout << "yes\n";
x = 10; cout << "expect yes "; if ( x < 9 ) cout << "yes\n";
x = 10; cout << "expect no ";
if ( x != 10 ) cout << "yes\n"; else cout << "no\n";

x = 10; cout << "expect no ";
if ( x > 10 ) cout << "yes\n"; else cout << "no\n";
2. Objects of `mstring` may be not initialized in declaration statements.

3. Objects of type `mstring` may participate in add(+, +=), subtract(-, -=), multiply(*, *=), divide(/, /=), modulo (%), (integers values only) pre/post increment/decrement (++/--), and concatenation (||) operations. The mode of the operation will depend on the mode of the other operand. Available modes: ASCII string, (char *) integer and floating point.

4. Objects of type `mstring` may participate in relational expressions >, >=, <, <=. The mode of comparison will depend on the mode of the other operand. Available modes ASCII string (char *), integer and floating point.

5. Objects of type `mstring` may participate in equality expressions == and !=. The mode of the comparison will depend on the mode of the other operand. Available modes ASCII string (char *), integer and floating point.

6. Objects of type `mstring` may participate in input and output stream operations >> and <<.

7. Objects of type `mstring` may not be assigned directly to ASCII string (char *) or `string`.

8. Objects of type `mstring` may be declared as arrays or allocated/freed by the new/delete operators. Only numeric subscripts permitted at this time.
If an object of type mstring is to be used in connection with the interpreter, it must be declared with a string giving its name in the runtime symbol table. For example:

```c++
mstring x("x");
```

If this is done, variables in the C++ program are linked to variables of the same name in the interpreter. That is, values from variables in the C++ program are known by the same name to interpreted programs invoked by the C++ program. Changes made to these variables in the interpreter are changes to the variables in the C++ program. Variable names selected must be compatible with the interpreter's naming conventions.

### 8 Direct Btree Access

Programmers may access the btree directly through the builtin BTREE macro. A number of examples can be found in `mumpsc/doc/examples/btree` in the distribution.

To access the btree directly from a C++ program:

You must first install the Mumps compiler and MDH. Include at the beginning of your program. You can now access the btree directly with the BTREE macro (see description below). Note: any keys you store in the btree co-exist with Mumps/MDH keys. In rare cases, these can interfere with one another if a key you store lies in the range of a global array key set.

For example, the following program stores NBR_ITERATIONS (defined in btree.h which is included by libmpscpp.h usually with the value 100,000) of keys and data into the btree and then retrieves them (this “btest1.cpp” from mumpsc/doc/examples/btree.cpp). See the other examples and the documentation below for further details.

```c++
#include <mumpsc /libmpscpp.h>

int main() {
```
long i,j;
unsigned char key[1024],data[1024];

printf("Store sequentially ascending keys");

for (i=0; i<NBR_ITERATIONS; i++) {
    sprintf((char *) key,"key %ld",i);
    sprintf((char *) data,"%ld%c",i,0);
    if (!BTREE(STORE,key,data)) {
        printf("error\n");
        return 1;
    }

    if (i%60000L==0) { printf("\n %ld ",i); fflush(stdout); }
    if (i%1000==0) { putchar('.'); fflush(stdout); }
    }

printf("\nretrieve");
for (i=0; i<NBR_ITERATIONS; i++) {
    sprintf((char *) key,"key %ld",i);
    if (!BTREE(RETRIEVE,key,data)) {
        printf("error 1\n");
        return 1;
    }

    sscanf((char *) data,"%ld",&j);
    if (j!=i) {
        printf("error 2\n");
        printf("%d != %d\n",i,j);
        return 1;
    }

    if (i%60000L==0) { printf("\n %ld ",i); fflush(stdout); }
    if (i%1000==0) { putchar('.'); fflush(stdout); }
    }

printf("\nlooks good!\n");
strcpy((char *) key,"");
strcpy((char *) data,"");
BTREE(CLOSE,key,data);
return 1;
}

9 Function and Macro Library

The following gives details on all the MDH functions and macros. Many have the same or similar syntax to the underlying legacy functions. The discussion assumes that &quot;gbl&quot; has been declared as above. The example indices (&quot;a,b,c&quot;) are for illustration purposes. Your actual globals array reference will be different. Many of the functions below mimic the same legacy functions. Please note that not all functions accept all possible argument data types. Check the function definition below for details.

9.1 Global Array Operations Using Class global

9.1.1 Arithmetic Operations on Global Arrays

The operations of add, subtract, multiply, divide, pre/post increment and pre/post decrement are defined (overloaded) for global variables. The operations are defined for mstring, short, unsigned short, int, unsigned int, long, unsigned long, float and double. Note: the contents of the global array node must be compatible with the dominant data type of the operation. If the contents of a global are not compatible with the operation (example, incrementing a string of text), the value of the global will be interpreted as zero. Examples:

```
#include &lt;mumps /libmmpscpp.h&gt;
```
global gbl("gbl");

int main () {

    // test of globals
    // gbl001.cpp

    int i, j=10;
    string a = "10", b = "20", c = "30";
    gbl.Kill();
    gbl(a, b, c) = 10;
    i = gbl(a, b, c) + 20;
    cout << "expect 20 " << i << endl; // prints 30

    i = 20 + gbl(a, b, c);
    cout << "expect 30 " << i << endl; // prints 30

    i = gbl(a, b, c) / j;
    cout << "expect 1 " << i << endl; // prints 1

    i = gbl(a, b, c) * 2;
    cout << "expect 20 " << i << endl; // prints 20

    gbl(a, b, c) ++;
    cout << "expect 11 " << gbl(a, b, c) << endl; // prints 11

    gbl(a, b, c) --;
    cout << "expect 10 " << gbl(a, b, c) << endl; // prints 10

    i = ++ gbl(a, b, c);
    cout << "expect 11 11 " << i << " " << gbl(a, b, c) << endl; // prints 11

    i = gbl(a, b, c) ++;
    cout << "expect 11 12 " << i << " " << gbl(a, b, c) << endl; // prints 11 12

    gbl(a, b, c) += 10;
    cout << "expect 22 " << gbl(a, b, c) << endl; // prints 22

    gbl(a, b, c) -= 10;
    cout << "expect 12 " << gbl(a, b, c) << endl; // prints 12

    gbl(a, b, c) *= 2;
    cout << "expect 24 " << gbl(a, b, c) << endl; // prints 24

    gbl(a, b, c) /= 2;
    cout << "expect 2 " << gbl(a, b, c) << endl; // prints 2

    GlobalClose;
    return 0;
}

9.1.2 Assignment Operations on Global Arrays

Assignments to global arrays may be accomplished the assignment operator (=).
When you access a global array, the access may result in the thrown error exceptions
*GlobalNotFoundException* and/or *ConversionException*. The first can occur in any context that
attempts to retrieve data from a global array where none exists. The second occurs if you attempt to
convert the contents of a global to a numeric type where the contents of the global are not valid data
for the conversion.

If uncaught, both exceptions will result in program termination. Both exceptions may be caught,
however, with code such as the following:

```cpp
#include <mumpsc /libmpscpp.h>
global a("a");

// gbl003.cpp
int main() {
    long i;
    a.Kill();
    a("1") = "now is the time";
    cout << "expect error message" << endl;

    try {
        i = a("1");
    } catch (ConversionException ce) {
        cout << ce.what() << endl;
    }
    cout << "expect error message" << endl;

    try {
        i = a("22");
    } catch (GlobalNotFoundException nf) {
        cout << nf.what() << endl;
    }
    cout << GlobalClose;
    return 0;
}
```

You may assign data of the following types directly to global arrays: *char*, *int*, *string*, *mstring*,
*double*, *global*, *unsigned int*, *float*, *short*, *unsigned short*, *long*, and *unsigned long*. You may
assign global arrays directly to variables of the following types: *int*, *mstring*, *double*, *global*,
*unsigned int*, *float*, *short*, *unsigned short*, *long*, and *unsigned long*.

### 9.1.3 Global Array Access and Manipulation Functions

#### 9.1.3.1 Accessing the Value Stored in a Global Array Element

```cpp
int global::Int();
double global::Double();
mstring global::Mstring();
char * global::Char(char * buf, int max);
```
The functions return the content of the invoking global array object converted to the named data type.

The \texttt{Char()} function is passed the address of a character array. The null-terminated character string contents of the global array element will be placed in the character array and the address of the array returned.

The \texttt{max} argument for \texttt{Char()} limits the length of the string returned to \texttt{max-1}.

If the global array element does not exist, the \texttt{GlobalNotFoundException} exception is thrown. If there is an error in converting the contents of the global to the named data type, a \texttt{ConversionException} is thrown.

Examples:

```cpp
#include <mumps/libmpscpp.h>

global t("t");

int main() {
   // gbl002.cpp

   int a;
   float b;
   mstring c;
   mstring x;
   char d[100];

   t.Kill();
   x=50; t(x)=99;

   a=t(x).Int();
   cout << "expect 99 " << a << endl;

   b=t(x).Double();
   cout << "expect 99 " << b << endl;

   c=t(x).Mstring();
   cout << "expect 99 " << c << endl;

   t(x).Char(d,100);
   cout << "expect 99 " << d << endl;

   GlobalClose;
}
```

9.1.3.2 \texttt{Data()}

The function \texttt{Data()} returns an integer which indicates whether the global array node is defined. The value returned is 0 if the global array node is undefined, 1 if it is defined and has no descendants; 10 if it is defined but has no value stored at the node (but does have descendants); and 11 it is defined and has descendants.

If a global array with no indices is passed to these functions, a value of "10" will be returned if the array exists and "0" if the array does not exist. For example:
Given:
  global gbl("gbl");
global non("non");
gbl("1","11")="foo"
gbl("1","11","21")="bar"

Then:
  gbl("1").Data() // 10 – node exists, has no data, has children
  gbl("1","11").Data() // 11 – node exists, has data and has children
  gbl("1","11","21").Data() // 1 – nodes exists, has data, no children

9.1.3.3 TreePrint()

  void global::TreePrint([[int indt [, const char indtchr]]]);

The invoking object is printed as an indented tree. If one argument is present (indt), it is the amount of indentation. If the second argument is present (indtchr) it is the character used in the indentation. The default indentation character is blank and the default amount of indentation is one. Example:

```cpp
#include <mumpsc/libmpscpp.h>

global d("d");

int main() {

  mstring a,b,c;

  for (int i = 1; i < 6; i++)
    for (int j = 1; j < 6; j++)
      for (int k = 1; k < 6; k++) {
        a = mcvt(i);
        b = mcvt(j);
        c = mcvt(k);
        d(a) = rand() % 100;
        d(a,b) = rand() % 100;
        d(a,b,c) = rand() % 100;
      }

d().TreePrint(1,'.');

GlobalClose;

return 0;
}

Yields

1=82
.1=59
..1=77
..2=35
..3=49
..4=27
..5=63
..6=67
..7=26
..8=11
2=68
.1=54
..1=96
..2=45
..3=21
..4=88
..5=99
..6=78
..7=76
..8=12

3=72
.1=28
..1=96
..2=45
..3=21
..4=88
..5=99
..6=78
..7=76
..8=12

4=66
.1=48
..1=96
..2=45
..3=21
..4=88
..5=99
..6=78
..7=76
..8=12

5=79
.1=72
..1=76
..2=7
..3=79
..4=12
..5=59
..6=21
..7=20
..8=6
```
9.1.3.4 UnLock()

```cpp
int global::UnLock()
```

UnLock() removes a lock from the designated node.

9.1.3.5 Count()

```cpp
long global::Count()
```

Returns the number of data bearing nodes beneath the given global array reference. Example:

```cpp
#include <mumps/libmpscpp.h>

global A("A");

int main() {
    mstring i,j;
    for (i=1; i<11; i++)
        for (j=1; j<11; j++) {
            A(i,j) = 5;
        }
    cout << "Full count: " << A().Count() << endl;
    cout << "A row count: " << A("5").Count() << endl;
    return EXIT_SUCCESS;
}
```

Yields

```
Full count: 100
A row count: 10
```

9.1.3.6 GlobalGet(), GlobalData(), GlobalSet()

```cpp
mstring GlobalGet (mstring global_ref)
char * GlobalGet (char * global_ref)
```
mstring GlobalOrder (mstring global_ref, int direction)
char * GlobalOrder (char * global_ref, int direction)

int GlobalData (mstring global_ref)
int GlobalData (char * global_ref)

int GlobalSet (mstring global_ref, mstring source)
int GlobalSet (mstring global_ref, char * source)
int GlobalSet (char * global_ref, mstring source)

These functions use the interpreter. These functions are used to permit runtime construction and access to global arrays. In both cases global_ref is a string containing a global array reference. This string can be dynamically constructed at runtime or may be read from a file or another global. Note: as this facility uses the interpreter, global array references must be preceded by the circumflex character (^).

In the case of the GlobalGet() functions, the string global array reference is interpreted and the value stored at the reference returned. If the reference is invalid or no data is stored, the value returned is the empty string and $test is set to false (zero). If a value is found, $test is set to true and the value is returned.

GlobalOrder() gives the next or prior value of the last index of the global array reference depending upon if direction is 1 (next) or -1 (prior). $test is set to 0 in the event of an error and 1 if there is no error. See Order().

GlobalData() returns a number indicating if the node exists and has descendants (see Data()). $test is set to 0 if there i>s an error, 1 otherwise. In the case of the GlobalSet() functions, the second argument is a string of data to be stored at the global array reference. The runtime routines will interpret the global_ref and assign the source to it. The value returned is one if successful ($test is set to 1), zero if not successful ($test set to 0). Examples:

```c
mstring a,b;
a = "^x("1")";
b = "test string";
if (GlobalSet(a,b) != 0) cout << "error\n";
```

These functions can be used to allow a program to create a text string global array reference and then use the string to address the global. Note that the target must contain either quoted literals or variables previously instantiated to the interpreter environment (see $SymSet() and SymGet()).

Generally speaking, these functions will be only used for dynamically constructed global array references. Most access to globals will be by overloaded shift or assignment operators.

9.1.3.7 double HitRatio(void)

Calculates the native global array processor cache hit ratio since the beginning of the program or the last call to HitRatio(). The native global array file processor, as opposed to the Berkeley Database Base, keeps track of how many file I/O requests are satisfied from data already in the file system’s cache. This function gives the percentage of cache hits. It only works with the native global array processor.

9.1.3.8 Kill()

void global:::Kill()

This function deletes a node and all its descendants. Examples:

```c
gbl().Kill(); // kill entire global array "gbl"
gbl(a,b,c).Kill(); // kill stated node and all descendants
```
9.1.3.9 Length()

```cpp
int mstring::Length()
int mstring::Length(char * pattern_string)
int mstring::Length(mstring pattern_string)
```

The function returns the string length of the invoking `mstring`. For example:

```cpp
x="ABC";
cout << x.Length() << endl; // writes 3
x="abcabcabcabc";
cout << x.Length("abc") << endl; // writes 5
```

If an argument is given, the function returns the number of non-overlapping occurrences of "pattern_string" in the source string plus 1.

9.1.3.10 int global::Lock()

Creates a lock on the named node. If successful, "$test" will be true (1), false (0) otherwise. Returns a 1 if the lock succeeds and a 0 otherwise.

The "Lock()" function marks a portion of the data base for exclusive access for an individual user. The "UnLock()" frees prior locks (see below). The locks are stored in a file named "Mumps.Locks" which is opened for exclusive access by the locking/unlocking job. The contents of the file may be deleted to remove all locks. A lock does not actually prevent access to a global but merely marks it as locked. If another task attempts to place a lock on a locked node, the descendant of a locked node or a direct parent of a locked node, the lock attempt will fail. Examples:

```cpp
if (gbl(a,b,c).Lock()) { ..... } // locks gbl(a,b,c) and all children;
if ($lock(gbl(a,b,c))) { ..... }
```

See also: CleanLocks(), CleanAllLocks(), and UnLock().

9.1.3.11 double global::Max()

Returns the maximum numeric value of the data bearing nodes beneath the given reference. Non-numeric values are treated as zeros. Example:

```cpp
#include <mumps/libmumps.cpp>
global A("A");
int main() {
  mstring i,j;
  for (i=1; i<11; i++)
    for (j=1; j<11; j++) {
      A(i,j) = rand()%1000;
    }
  cout << "Max value of all: " << A().Max() << endl;
  cout << "Max value of row 10: " << A("10").Max() << endl;
  return EXIT_SUCCESS;
}
```

Yields:

Max value of all: 996
Max value of row 10: 932

9.1.3.12 int global::Merge(global)

Copies the first `global` and its descendants to the second `global`. The Merge() function copies from one array to another. Examples:

```cpp
Xecute("for i=1:1:9 for j=1:1:9 set ^a(i,j)=i+j");
```
c().Merge(a()); // copies all of ^a to ^c

Xecute("for i=100:1:109 s ^b(i)=i");

b("103").Merge(a("3")); // copies ^a(3) to ^b(103) and children of
// ^a(3) to be children of ^b(103)

d(" ").Merge(a("3")); // creates ^d=^a(3); ^d(1)=^a(3,1),...

\subsection{double global::Min()}

Returns the minimum numeric value of the data bearing nodes beneath the given reference. Non-
umeric values are treated as zeros. Example:

```cpp
#include <mumps /libmpscpp.h>
global A("A");

int main() {
  mstring i,j;
  for (i=1; i<11; i++)
    for (j=1; j<11; j++) {
      A(i,j) = rand()%1000;
    }
  cout << "Min value of all: " << A().Min() << endl;
  cout << "Min value of row 10: " << A("10").Min() << endl;
  return EXIT_SUCCESS;
}
```

Yields:

Min value of all: 11
Min value of row 10: 12

\subsection{Multiply()}

\textbf{void} global::Multiply\textbf{(global} B,\textbf{global} C)

The invoking global is multiplied by \textit{B} and the result is place in \textit{C}. The number of columns of \textit{A} must equal the number of rows of \textit{B}. The resulting matrix \textit{C} will have "n" rows and "m" columns
where "n" is the number of rows of "A" and "m" is the number of columns of "B".

In all cases \textit{C} will be deleted before the operation commences. The data stored at each node must
be numeric. All calculations are performed in \textbf{double} precision arithmetic. Each matrix must be two
dimensional. Example:

```cpp
#include <mumps/libmpscpp.h>
#include <mumps/libmpsrdbms.h>

global d("d");
global e("e");
global f("f");

int main() {
  d("1","1")=2;
  d("1","2")=3;
  d("2","1")=4;
  d("2","2")=-1;
  d("3","2")=0;
  d("3","2")=4;
```
\[ e(1,1) = 5; \]
\[ e(1,2) = -2; \]
\[ e(1,3) = 4; \]
\[ e(1,4) = 7; \]
\[ e(2,1) = -6; \]
\[ e(2,2) = 1; \]
\[ e(2,3) = -3; \]
\[ e(2,4) = 0; \]

\[ d().Multiply(e(),f()); \]
\[ PRINT("f","1"); \]

\[ return \ EXIT\ SUCCESS; \]
\[
\]
\[ Yields: \]
\[ ^f(1,1) = -8 \]
\[ ^f(1,2) = -1 \]
\[ ^f(1,3) = -1 \]
\[ ^f(1,4) = 14 \]
\[ ^f(2,1) = 11 \]
\[ ^f(2,2) = -3 \]
\[ ^f(2,3) = 7 \]
\[ ^f(2,4) = 7 \]
\[ ^f(3,1) = -24 \]
\[ ^f(3,2) = 4 \]
\[ ^f(3,3) = -12 \]
\[ ^f(3,4) = 0 \]

9.1.3.15 Name()

\[ \text{mstring global::Name()} \]

Returns a null terminated pointer to array of characters containing of the \texttt{global} reference with all variables and expressions in the indices evaluated. Example:

\[ \text{#include <mumps/libmpscpp.h> } \]
\[ \text{global a("a");} \]
\[ \text{int main()} \{ \}
\[ \text{mstring b="1",c=2",d="3";} \]
\[ \text{cout << a(b,c,d,c+d).Name() << endl; \}
\[ \text{return EXIT\_SUCCESS;} \]
\[
\]
\[ Yields: \]
\[ a("1","2","3","23") \]

9.1.3.16 Order()

\[ \text{mstring global::Order([int direction])} \]

The \texttt{Order()} function gives the next ascending or descending value of the last index in a global array reference. The direction, ascending or descending, is given by either the name of the function or an integer “direction” which is either 1 - next ascending index, or -1 - next descending index. If ‘direction’ is omitted, ascending is assummed. For example, if an array named "test" has nodes:

\[ \text{given:} \]
\[ \text{global test("test");} \]
Then Order() will return the following values:

<table>
<thead>
<tr>
<th>Test Case</th>
<th>Order(1)</th>
<th>Order(-1)</th>
</tr>
</thead>
<tbody>
<tr>
<td>test().Order(1)</td>
<td>yields &quot;1&quot;</td>
<td>yields 5</td>
</tr>
<tr>
<td>test(&quot;1&quot;,&quot;&quot;).Order(1)</td>
<td>yields &quot;10&quot;</td>
<td>yields &quot;1&quot;</td>
</tr>
<tr>
<td>test(&quot;1&quot;,&quot;10&quot;).Order(1)</td>
<td>yields 20</td>
<td>yields &quot;1&quot;</td>
</tr>
<tr>
<td>test(&quot;1&quot;,&quot;20&quot;).Order(1)</td>
<td>yields &quot;&quot; (empty string)</td>
<td>yields &quot;2&quot;</td>
</tr>
<tr>
<td>test(&quot;5&quot;,&quot;&quot;).Order(1)</td>
<td>yields &quot;&quot; (empty string)</td>
<td>yields &quot;&quot; (empty string)</td>
</tr>
<tr>
<td>test(&quot;5&quot;,&quot;1&quot;).Order(1)</td>
<td>yields &quot;2&quot;</td>
<td>yields &quot;&quot; (empty string)</td>
</tr>
<tr>
<td>test(&quot;5&quot;,&quot;2&quot;).Order(1)</td>
<td>yields &quot;&quot; (empty string)</td>
<td>yields &quot;&quot; (empty string)</td>
</tr>
</tbody>
</table>

Similarly, a direction code of -1 will reverse the process:

- test().Order(-1) yields 5
- test("5").Order(-1) yields "1"
- test("1").Order(-1) yields "" (empty string)

Use the empty string (""") to get the initial value of an index. When there are no further values, the empty string is returned.

Note: all keys are stored in ASCII character collating order. This means that numeric keys are sorted alphabetically rather than numerically.

9.1.3.17 Avg()

declare global::Avg()

Returns the average of the values of data bearing nodes beneath the given global array reference. Example:

```cpp
#include <mumpsc/libmpscpp.h>

global A("A");

int main() {
    // gbl004.cpp
    mstring i,j;
    A.Kill();
    for (i=0; i<1000; i++)
        for (j=1; j<10; j++) {
            A(i,j) = j;
        }
    cout << A("100").Avg() << endl; // average of nodes below A("100")
    cout << A().Avg() << endl; // average of all nodes
    GlobalClose;
    return 0;
```
The above prints 5.5 - the average value of numeric data bearing nodes beneath A("100"). If there are non-numeric data elements, they are treated as a zero values and contribute to the result.

The global array object must be specified with indices (i.e., a parenthesized list must follow the name of the global array object. An empty list means the entire array.

9.1.3.18 CleanLocks(), CleanAllLocks()

```
void CleanLocks(void)
void CleanAllLocks(void)
```

"CleanLocks()" removes all locks for the current process. "CleanAllLocks()" removes all locks for all processes for which the current directory is the default directory. Locks are implemented by entries in a file named "Mumps.Locks" created and maintained in the current directory. This file must be read/write enabled for the current process. You may also delete all locks by removing this file. Locks are discussed elsewhere but, in brief, they are used to signal ownership of a portion of a global array. When a lock has been applied to a node, no other process may lock this node, any descendant node or any parent node. Locking does not actually prevent access, it merely marks a resource as locked.

9.1.3.19 GlobalClose

This macro closes the global array files. The global arrays must be closed on exit or they will be corrupt. The macro causes the file system to flush all its buffers and cache and close the file system. Normally, a "GlobalClose" is executed automatically when your program ends except if your program is terminated by SIGKILL or SIGSTOP (which cannot be trapped). If your program is using a large memory based cache (cache's can be 1 GB or more, on some systems), there may be a noticeable delay in file system shutdown due to the time required to write the cache to disk.

9.1.3.20 Btree()

```
int BTREE(int code, unsigned char * key, unsigned char * data)
```

BTREE() is a macro permitting direct access to the underlying btree system. The first argument, "code" is an integer indicating the operation to be performed (see below). The second argument is the key to be stored consisting of a null-terminated array printable ASCII characters. The length of the key should be no greater than one quarter of the btree block size whose default value is 8192 (i.e., max key length is about 2048 bytes in the default case). The third argument is the data to be stored with the key. It is a null-terminated string of printable ASCII characters not greater than the system defined limit STR_MAX (defaults to 4096). An empty string is interpreted as no data to be stored. Note that the second and third arguments must be unsigned char *. The macro returns an integer indicating success. It may also alter "key" or "data" to return values or for other purposes. The contents of "key" and "data" are not preserved across in invocation of BTREE() Examples of using BTREE() are given in mumpsc/doc/examples/btree.

Permitted btree operations:

1. STORE - store a key and data value in the btree; retuns zero if successful, non-zero otherwise:

   ```
   unsigned char key[]="test key";
   unsigned char data[]="test data";
   if ( BTREE(STORE,key,data) == 0 ) cout << "stored" << endl;
   else cout << "not stored" << endl;
   ```

2. RETRIEVE - retrieve data stored with a key; returns zero if successful, non-zero otherwise:

   ```
   unsigned char key[]="test key";
   unsigned char data[STR_MAX];
   if ( BTREE(RETRIEVE,key,data) == 0 ) cout << "retrieved: " << data << endl;
   ```
else cout << "not retrieved." << endl;

3. CLOSE - close the btree data base; returns zero:

```c
unsigned char key[]="";
unsigned char data[]="";
BTREE(CLOSE,key,data);
```

4. XNEXT/PREVIOUS - retrieve next ascending/descending key; returns one. Value of second and third arguments become the value of the next ascending/descending key. An initial value of the empty string for the second argument will retrieve the first/last key and the value of the second argument becomes the empty string when there are no more ascending/descending values. An initial value of the empty string for the second argument will retrieve the first/last key.

```c
unsigned char key[]="";
unsigned char data[STR_MAX];
printf("\nbegin retrieve...
");
while(1) { // retrieve keys in ascending order
   i=BTREE(XNEXT,key,data);
   if (strlen((char *) data)==0) break;
   cout << key << endl;
}
```

9.1.3.21 Query functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>mstring Query(mstring ref)</td>
<td></td>
</tr>
<tr>
<td>mstring Query(char * ref)</td>
<td></td>
</tr>
<tr>
<td>int Qlength(mstring ref)</td>
<td></td>
</tr>
<tr>
<td>int Qlength(char * ref)</td>
<td></td>
</tr>
<tr>
<td>mstring Qsubscript(mstring ref, mstring index)</td>
<td>returns the index'th subscript of a global array reference.</td>
</tr>
<tr>
<td>mstring Qsubscript(mstring ref, int index)</td>
<td></td>
</tr>
<tr>
<td>mstring Qsubscript(char * ref, int index)</td>
<td></td>
</tr>
</tbody>
</table>

Query() returns an mstring containing the next global array reference in the data base or the empty string.

Qlength() returns the number of subscripts in the global array reference.

Qsubscript() returns the index'th subscript of a global array reference.

Each of these functions operates on a text representation of a global array reference. See also the Name() function. The following example makes use of the MeSH subject headings (National Library of Medicine). The MeSH global array was constructed with statements such as:

```c
set ^mesh("A01")="Body Regions"
set ^mesh("A01","047")="Abdomen"
set ^mesh("A01","047","025")="Abdominal Cavity"
set ^mesh("A01","047","025","600")="Peritoneum"
set ^mesh("A01","047","025","600","225")="Douglas' Pouch"
set ^mesh("A01","047","025","600","451")="Mesentery"
set ^mesh("A01","047","025","600","451","535")="Mesocolon"
set ^mesh("A01","047","025","600","573")="Omentum"
set ^mesh("A01","047","025","600","678")="Peritoneal Cavity"
set ^mesh("A01","047","025","750")="Retroperitoneal Space"
set ^mesh("A01","047","050")="Abdominal Wall"
set ^mesh("A01","047","365")="Groin"
set ^mesh("A01","047","412")="Inguinal Canal"
set ^mesh("A01","047","849")="Umbilicus"
set ^mesh("A01","176")="Back"
```
set `mesh("A01","176","519")="Lumbosacral Region"
set `mesh("A01","176","780")="Sacrococcygeal Region"
set `mesh("A01","236")="Breast"
set `mesh("A01","236","500")="Nipples"
set `mesh("A01","378")="Extremities"
set `mesh("A01","378","100")="Amputation Stumps"
set `mesh("A01","378","610")="Lower Extremity"
set `mesh("A01","378","610","100")="Buttocks"
set `mesh("A01","378","610","250")="Foot"
set `mesh("A01","378","610","250","149")="Ankle"
set `mesh("A01","378","610","250","300")="Forefoot, Human"
set `mesh("A01","378","610","250","300","480")="Metatarsus"
set `mesh("A01","378","610","250","300","792")="Toes"
set `mesh("A01","378","610","250","792","380")="Hallux"
set `mesh("A01","378","610","250","510")="Heel"
set `mesh("A01","378","610","400")="Hip"
set `mesh("A01","378","610","450")="Knee"
set `mesh("A01","378","610","500")="Leg"
set `mesh("A01","378","610","750")="Thigh"
set `mesh("A01","378","800")="Upper Extremity"
set `mesh("A01","378","800","075")="Arm"
set `mesh("A01","378","800","090")="Axilla"
set `mesh("A01","378","800","420")="Elbow"
set `mesh("A01","378","800","585")="Forearm"
set `mesh("A01","378","800","667")="Hand"
set `mesh("A01","378","800","667","430")="Fingers"
set `mesh("A01","378","800","667","715")="Wrist"
set `mesh("A01","378","800","750")="Shoulder"

#include <mumpsc/libmpscpp.h>

//     CompiledMtree1.cpp Feb 28, 2007

int main() {

  global mesh("mesh");
  mstring x;
  int i,j;

  x=Query("^mesh(0)");
  while (1) {
    x=Query(x);
    if (x=="") break;
    if ((x.Piece("(",1)!="^mesh") break;
    i=Qlength(x);
    for (j=0; j<i; j++) cout << "   ";
    cout << Qsubscript(x,i) << " " << x.Eval() << endl;
  }

  return 0;
}

which yields:

047 Abdomen
025 Abdominal Cavity

### 9.1.3.22 Similarity functions: Sim1(), Cosine(), Jaccard(), Dice()\

```c++
double global::Sim1(global B)
double global::Cosine(global B)
double global::Jaccard(global B)
double global::Dice(global B)
```

The global arrays referenced by the invoking object and the passed object are compared and a similarity value is computed. The functions compute the similarities of the data bearing nodes beneath the global array references.

These are some commonly used similarity metrics. (see Salton, G; and McGill, M, *Introduction to Modern Information Retrieval*, McGraw Hill, 1983).
For example:

```cpp
#include <mumpsc/libmpscpp.h>

global A("A");
global B("B");

int main() {
    A("1","1","1") = 1;
    A("1","1","2") = 1;
    A("1","1","3") = 1;
    A("1","1","5") = 1;

    B("1","1","1") = 1;
    B("1","1","2") = 1;
    B("1","1","4") = 1;
    B("1","1","6") = 1;

    cout << A("1","1").Sim1(B("1","1")) << endl;

    GlobalClose;
    return 0;
}
```

The above prints 2 since there are two nodes in common below the "1,1" levels.

```cpp
#include <mumpsc/libmpscpp.h>

global A("A");
global B("B");

int main() {
    A("1","1","1") = 2;
    A("1","1","2") = 1;
    A("1","1","3") = 1;
    A("1","1","5") = 1;

    B("1","1","1") = 2;
    B("1","1","2") = 1;
    B("1","1","4") = 1;
    B("1","1","6") = 1;

    cout << A("1","1").Sim1(B("1","1")) << endl;

    GlobalClose;
    return 0;
}
```

The above prints 5 since there are two nodes in common below the "1,1" levels but one of the set of nodes in common have a stored value of 2. (2*2+1*1)

```cpp
#include <mumpsc/libmpscpp.h>

global A("A");
global B("B");
```
#include <mumpsc/libmpscpp.h>

global A("A");
global B("B");

int main()
{
    A("1") = 3;
    A("2") = 2;
    A("3") = 1;
    A("4") = 0;
    A("5") = 0;
    A("6") = 0;
    A("7") = 1;
    A("8") = 1;

    B("1") = 1;
    B("2") = 1;
    B("3") = 1;
    B("4") = 0;
    B("5") = 0;
    B("6") = 1;
    B("7") = 0;
    B("8") = 0;

    cout << A().Jaccard(B()) << endl;

    GlobalClose;

    return 0;
}

prints 1
global B("B");

int main() {
    A("1") = 3;
    A("2") = 2;
    A("3") = 1;
    A("4") = 0;
    A("5") = 0;
    A("6") = 0;
    A("7") = 1;
    A("8") = 1;

    B("1") = 1;
    B("2") = 1;
    B("3") = 1;
    B("4") = 0;
    B("5") = 0;
    B("6") = 1;
    B("7") = 0;
    B("8") = 0;

    cout << A().Dice(B()) << endl;
    GlobalClose;

    return 0;
}

prints 1

#include <mumpsc/libmpscpp.h>

global A("A");
global B("B");

int main() {
    A("1") = 3;
    A("2") = 2;
    A("3") = 1;
    A("4") = 0;
    A("5") = 0;
    A("6") = 0;
    A("7") = 1;
    A("8") = 1;

    B("1") = 1;
    B("2") = 1;
    B("3") = 1;
    B("4") = 0;
    B("5") = 0;
    B("6") = 1;
    B("7") = 0;
    B("8") = 0;

    cout << A().Cosine(B()) << endl;
9.1.3.23 Transpose()

```cpp
void global::Transpose(global out)
```

The invoking object is transposed and the result is placed in `out`. Any prior contents of the array `out` are deleted before the operation commences. Example:

```cpp
#include <mumps/libmpscpp.h>
#include <mumps/libmpsrdbms.h>

global d("d");
global f("f");

int main() {
    d("1","1")=2;
d("1","2")=3;
d("2","1")=4;
d("2","2")=0;

d().Transpose(f()); // transpose d() placing result in f()

cout << f("1","1") << " " << f("1","2") << endl;
cout << f("2","1") << " " << f("2","2") << endl;

GlobalClose;
return EXIT_SUCCESS;
}

Yields:
2 4
3 0
```

9.1.3.24 Centroid()

```cpp
void global::Centroid(global B)
```

A centroid vector `B` is calculated for the invoking two dimensional global array. The centroid vector is the average value for each for each column of the matrix. Any previous contents of the global array named to receive the centroid vector are lost. The invoking global array (A) must contain at least two dimensions. For example:

```cpp
#include <mumps/libmpscpp.h>
global A("A");
global B("B");

int main() {
    mstring i,j;
    for (i=0; i<10; i++)
        for (j=1; j<10; j++) {
            A(i,j) = 5;
        }
    A().Centroid(B());
```
mstring a="";
while (1) {
    a=B(a).Order(1);
    if (a=="") break;
    cout << a << " --> " << B(a) << endl;
}
return 0;
}

Yields:
1 --> 5
2 --> 5
3 --> 5
4 --> 5
5 --> 5
6 --> 5
7 --> 5
8 --> 5
9 --> 5

The above yields a vector giving the average value of each named column of the matrix "A" (5 in this case since each column is initialized with 5).

9.1.3.25 Correlation functionsL: TermCorrelate(), DocCorrelate()

    void global::TermCorrelate(global B)
    void global::DocCorrelate(global B, mstring fcnname, double threshold)

These functions build document indexing correlation matrices. The invoking global is assumed to be a two dimensional document-term matrix whose rows are documents and whose columns represent the occurrence of terms in the documents (either weights or frequencies).

TermCorrelate() builds a square term-term correlation matrix in B from the invoking document-term matrix.

DocCorrelate() builds a square document-document correlation matrix from the invoking document-term matrix. The name of the function to be used in calculating the document-document similarity is given in fcn and may be Cosine, Jaccard, Dice, or Sim1. The minimum correlation threshold is given in threshold which defaults to 0.80 if omitted.

TermCorrelate() Example:

#include <mumpsc/libmpscpp.h>
global A("A");
global B("B");
int main() {
long i,j;

    A("1","computer")=5;
    A("1","data")=2;
    A("1","program")=6;
    A("1","disk")=3;
    A("1","laptop")=7;
    A("1","monitor")=1;

    A("2","computer")=5;
    A("2","printer")=2;
    A("2","program")=6;
    A("2","memory")=3;
    A("2","laptop")=7;
A("2","language")=1;
A("3","computer")=5;
A("3","printer")=2;
A("3","disk")=6;
A("3","memory")=3;
A("3","laptop")=7;
A("3","USB")=1;

A().TermCorrelate(B());
mstring a;
mstring b;

a="";

while (1) {
    a=B(a).Order();
    if (a=="") break;
    cout << a << endl;
    b="";
    while (1) {
        b=B(a,b).Order(1);
        if (b=="") break;
        cout << "    " << b << "(" << B(a,b) << ")" << endl;
    }
}
return 0;
}

Yields:

USB
    computer(1)
    disk(1)
    laptop(1)
    memory(1)
    printer(1)
computer
    USB(1)
    data(1)
    disk(2)
    language(1)
    laptop(3)
    memory(2)
    monitor(1)
    printer(2)
    program(2)
data
    computer(1)
    disk(1)
    laptop(1)
    monitor(1)
    program(1)
disk
    USB(1)
    computer(2)
    data(1)
    laptop(2)
    memory(1)
    monitor(1)
The above gives the number of co-occurrences of each word with each other word. For example, the words "computer" and "memory" co-occur in two vectors (2 nd 3) while the words "laptop" and "computer" co-occur in all three vectors. If each vector is thought of as a document, the strength of the co-occurrences between words is a measure of similarity for indexing purposes.

DocCorrelate() Example:

```cpp
#include <mumpsc/libmpscpp.h>
```
global A("A");
global B("B");
int main() {
    long i,j;

    A("1","computer")=5;
    A("1","data")=2;
    A("1","program")=6;
    A("1","disk")=3;
    A("1","laptop")=7;
    A("1","monitor")=1;

    A("2","computer")=5;
    A("2","printer")=2;
    A("2","program")=6;
    A("2","memory")=3;
    A("2","laptop")=7;
    A("2","language")=1;

    A("3","computer")=5;
    A("3","printer")=2;
    A("3","disk")=6;
    A("3","memory")=3;
    A("3","laptop")=7;
    A("3","USB")=1;

    A().DocCorrelate(B(),"Cosine",.5);

    mstring a=
    mstring b;

    a=""

    while (1) {
        a=B(a).Order(1);
        if (a=="") break;
        cout << a << endl;
        b="
        while (1) {
            b=B(a,b).Order(1);
            if (b=="") break;
            cout << " " << b << "(" << B(a,b) << ")" << endl;
        }
    return 0;
}
Yields
1
2  0.887096774193548
   0.741935483870968
3
2  0.887096774193548
   0.701612903225806
3
1  0.741935483870968
   0.701612903225806
The above program calculates the similarities between the document vectors according to the Cosine method.

### 9.1.3.26 IDF()

```c++
void global::IDF(double DocCount)
```

The `IDF()` function calculates for the global array vector provided the inverse document frequency weight of each term. The vector should be indexed by words and have stored the number of documents in which each word occurs. The document count will be replaced by the calculated IDF value. The IDF is \( \log_2(DocCount/Wn) + 1 \) where \( Wn \) is the number of documents in which a term appears (the document frequency). The value `DocCount` is the total number of documents present in the collection. Example:

```c++
#include <mumpsc/libmpscpp.h>

global a("a");

int main() {
    kill(a());
    a("now")=2;
    a("is")=5;
    a("the")=6;
    a("time")=3;
    a().IDF(4);
    a().TreePrint();
    return 0;
}
```

Yields:

```
is=0.678072
now=2.000000
the=0.415037
time=1.415037
```

### 9.1.3.27 Sum()

```c++
double global::Sum()
```

The global array nodes beneath the referenced global array are summed. Non numeric quantities are treated as zero. Example:

```c++
#include <mumpsc/libmpscpp.h>

global A("A");

int main() {
  mstring i, j;

  for (i = 1; i < 11; i++)
    for (j = 1; j < 11; j++) {
      A(i, j) = 5;
    }

  cout << "Full sum: " << A().Sum() << endl;
  cout << "A row sum: " << A("5").Sum() << endl;
}
```
9.2 Mstring Operations and Manipulations

9.2.1 Arithmetic Operations on Mstrings

9.2.2 Assignment Operations on Mstrings

9.2.3 Functions of Class mstring

9.2.3.1 cvt()

```c
char * cvt(arg)
```

The function converts the argument to a null terminated character string. The arguments may be long, double, float, and int. Do not use this function more than once in an expression as the returned pointer is to a static variable in the function. Multiple calls will point to the same variable.

9.2.3.2 decorate()

```c
int string::decorate(mstring pattern, mstring left, mstring right)
```

Locates the pattern in the invoking `mstring` and inserts `left` immediately to the left of the string that matched the pattern and inserts `right` immediately to the right of the found pattern. Returns 1 if the pattern was found and the insertions were made, -1 if the pattern was not found, and less than -1 for other errors (see PCRE documentation concerning `pcre_exec()` return codes). Throws: `PatternException()`.

9.2.3.3 EncodeHTML()

```c
char * mstring EncodeHTML(char * arg)
mstring EncodeHTML(mstring arg)
```

Encodes the argument string according to HTML rules and returns the result. Alphabets and numbers are unchanged. Blanks become plus signs and all other characters replaced by "%xx" where "xx" is the hexadecimal value of the character in the ASCII collating sequence. The function is used mainly in connection with parameters passed with URL's which may not contain blanks or special characters. The code in `cgi.h` is used to decode these strings. Example:

```c
#include <mumps /libmpscpp.h>
int main() {
    char x[]="now is =()$.& the time";
    cout << EncodeHTML(x) << endl;
    return EXIT_SUCCESS;
}
```

Yields

```
now+is+%3D%28%29%24%2E%26+the+time
```

9.2.3.4 ends()

```c
int mstring::ends(mstring pattern)
```

```c
#include <mumps /libmpscpp.h>
int main() {
    char x[]="now is =()$.& the time";
    cout << EncodeHTML(x) << endl;
    return EXIT_SUCCESS;
}
```

Yields

```
now+is+%3D%28%29%24%2E%26+the+time
```
Returns an integer giving the character position (relative to zero) immediately following the string that matched *pattern*. Returns -1 if the string did not match. Throws: *PatternException*.

### 9.2.3.5 replace()

**int mstring::replace(mstring pattern, mstring replacement)**

Replaces the string matching *pattern* with *replacement*. Returns 1 if successful, 0 if there was no match and less than -1 on error (See PCRE documentation for pcre_exec()).

Throws: PatternException.

### 9.2.3.6 c_str()

**char * mstring::c_str()**

Returns a pointer to a null terminated `<b>char</b>` array containing the contents of the invoking mstring object.

### 9.2.3.7 s_str()

**string mstring::s_str()**

Returns a string copy of the contents of the invoking mstring object.

### 9.2.3.8 shred()

**mstring Shred(mstring str, int size)**

The Shred() function shreds the input string *str* into fragments of length *size* upon successive calls. The function returns a string of length zero when there are no more fragments of length *size* remaining (thus, short fragments at the end of a string are not returned). Shred() copies the input string to an internal buffer upon the first call. Subsequent calls retrieve from this buffer. When the buffer is consumed, the function will copy the contents of the next string submitted to the buffer.

Example:

```c
#include <mumpsc/libmpscpp.h>

int main() {
    char x[]="abcdefghijklmnopqrstuvwxyz";
    char *p;
    while(1) {
        p=Shred(x,5);
        if (strlen(p)==0) break;
        cout << p << endl;
    }
    return 0;
}
```

yields:

```
abcde
fghij
klmno
pqrst
uvwxy
```

### 9.2.3.9 begins()

**int mstring::begins(mstring pattern)**
Returns an integer which is the starting point in the string of pattern or -1 if the pattern is not found. Throws: PatternException if the pattern is in error.

9.2.3.10

9.2.3.11 c_str()

    char * mstring::c_str()

Returns a char * to a NULL terminated character string containing the same value as the mstring variable.

9.2.3.12 Justify()

    mstring mstring::Justify(int field_width[, int precision])

Justify() right justifies the invoking mstring in an mstring field whose length is given by the first argument. If the second argument is present and a positive integer, the invoking mstring is right justified in a field whose length is given by the first argument with "precision" decimal places. The two argument form imposes a numeric interpretation upon the first argument.

    x="39";
    x.Justify(3) yields " 39"

    x="TEST";
    x.Justify(7) yields " TEST"

    x="39";
    x.Justify(4,1) yields "39.0"

9.2.3.13 Extract()

    mstring mstring::Extract([int start, [int end]])

Returns an mstring containing a substring substring of the first argument. The substring begins at the position noted by the second operand. If the third operand is omitted, the substring consists only of the "start" character of invoking source string. If the third argument is present, the substring begins at position "start" and ends at position "end". If no argument is given, the function returns the first character of the string. If "end" specifies a position beyond the end of source string, the substring ends at the end of source string:. String position counting begins at one (not zero). For example:

    mstring x;
    x="ABCDEF";
    x.Extract(2) yields "B"
    x.Extract(3,5) yields "CDE"

9.2.3.14 Find()

    int mstring::Find(mstring pattern_string [, int start)
    int mstring::Find(const char * pattern_string [, int start)

Find() searches the first argument for an occurrence of the second argument. If one is found, the value returned is one greater than the end position of the second argument in the first argument. If "start" is specified, the search begins at position "start" in argument 1. If the second argument is not found, the value returned is 0. String position counting begins at position one. For example:

    mstring x;
    x="ABC";
    x.Find("B") yields 3
    x="ABCAABC";
    x.Find("A",3) yields 5
9.2.3.15 Horolog()

```c
mstring Horolog()
```

Returns a mstring containing of two numbers. The first is the number of days since December 31, 1840 and the second is the number of seconds since the most recent midnight. These values are relative to Greenwich Mean Time.

9.2.3.16 mcvt()

```c
mstring mcvt(arg)
```

Converts the arg to mstring. Arg may be int, char *, float long or double.

9.2.3.17 ascii()

```c
int mstring::Ascii()
int mstring::Ascii(int start)
```

Returns the numeric value of an ASCII character. If no start is specified, the numeric values of the first character of invoking mstring is used. If start is specified, the numeric value of start”th character of invoking is chosen. If the empty string is given, -1 is returned. For example:

```c
mstring a;
a="ABC";
a.Ascii() yields 65
a.Ascii(1) yields 65
a.Ascii(2) yields 66
```

9.2.3.18 Evaluate a Mumps Expression

```c
mstring mstring::Eval()
```

Evaluates the mumps expression of the invoking mstring object and returns the result in an mstring. If an error occurs, an InterpreterException is thrown. The invoking mstring object may contain a valid mumps expression involving calling program mstring variables.

9.2.3.19 Pattern()

```c
int mstring::Pattern(char * pattern_string)
int mstring::Pattern(mstring & pattern_string)
```

Evaluates the invoking source string according to the pattern string and returns 0 (does not match) or 1 (does match). Pattern string rules are as as shown below but you must remember to place a backslash before quotes in the pattern string (as per usual C++ rules). The pattern match function is used to determine if a string conforms to a certain pattern. Pattern match operations are converted to Perl Compatible Regular Expressions and are executed by functions in the PCRE library which must be present. You may access the PCRE directly, using Perl expression format with the "perl_pm(string, pattern, 1, svPtr)" function discussed in Appendix D.

The pattern codes are:

- A for the entire upper and lower case alphabet.
- C for the 33 control characters.
- E for any of the 128 ASCII characters.
- L for the 26 lower case letters.
- N for the numerics
- P for the 33 punctuation characters.
- U for the 26 upper case characters.
- A literal string.
A pattern code is made up of one or more of the above, each preceded by a count specifier. The count specifier indicates how many of the named item must be present. Alternatively, an indefinite specifier - a decimal point - may be used to indicate any count (including zero). For example:

```cpp
mstring A;
A="123-45-6789";
if (A.Pattern(command("3N1-"2N1-"4N"))) cout << "OK" << endl;
A="JONES, J. L.";
if (A.Pattern(command(".A1",".A") )) cout << "OK" << endl;
```

Full pattern matching syntax, including support for alternation, are supported as described in Appendix D of the Compiler manual. The macro "command()" will handle the required backslash escape characters required before quote marks.

**9.2.3.20 Perl()**

```cpp
int Perl(mstring string, mstring regex)
int Perl(mstring string, char * regex)
```

The regular expression in the null terminated character array or mstring given by regex is applied to the mstring string. If the pattern match succeeds, true (1) is returned, false (0) otherwise and $test is set accordingly. This macro also sets variables in the run-time symbol table. See SymGet() and SymPut() for details on accessing the symbol table. See Appendix D for examples of using this function.

**9.2.3.21 Piece()**

```cpp
mstring mstring::Piece(mstring pattern-string, int start[, int end])
mstring mstring::Piece(const char * pattern-string, int start[, int end])
```

The Piece() function returns a substring of the invoking mstring delimited by the instances of the first argument. The substring returned in the two argument case is that substring of the invoking mstring that lies between the "start" minus one and "start" occurrence of the first argument. In the three argument form, the string returned is that substring of the invoking mstring delimited by the "start" minus one instance of the first argument and the end'th instance of the first argument. If only two arguments are given, end is assumed to be start. For example:

```cpp
x="aaa.bbb.ccc.eee.fff";
cout << x.Piece( ".",1) << endl; // writes aaa
cout << x.Piece(".",2) << endl; // writes bbb
cout << x.Piece(".",5) << endl; // writes fff
cout << x.Piece(".",4,5) << endl; // writes eee.fff
```

Global arrays may be used in any argument position but only one instance of the same global may appear (see note in Accessing global arrays section).

**9.2.3.22 ShredQuery()**

```cpp
mstring ShredQuery(mstring str, int size)
```

The ShredQuery() function shreds size shifted copies of the input string str into fragments of length size upon successive calls. That is, the function first returns all the size fragments of the string in the same manner as Shred(). However, it then shifts the starting point of the input string to the right by one and returns all the size length fragments relative to the shifted starting point. It repeats this process a total of size times.

The function returns a string of length zero when there are no more fragments of length size remaining (thus, short fragments at the end of a string are not returned). ShredQuery() initially copies the input string to an internal buffer upon the first call. Subsequent calls retrieve from this buffer. When the buffer is consumed, the function will copy the contents of the next string submitted to the buffer. Example:
#include <mumpsc/libmpscpp.h>

int main() {
    char x[]="abcdefghijklmnopqrstuvwxyz";
    char *p;
    while(1) {
        p=ShredQuery(x,5);
        if (strlen(p)==0) break;
        cout << p << endl;
        return 0;
    }
}

Yields:

abcde
fghij
klmno
pqrst
uvwxy

bcdef
ghijk
lmnop
qrstu
cdefg
hijkl
mnopq
rstuv
defgh
ijklm
nopqr
stuvw
efgih
jklnm
opqrs
tuvwx

9.2.3.23 Stem()

**mstring** stem(mstring & word)

Returns the original word or the English linguistic root stem of the word, if one can be found.

9.2.3.24 Readline()

```cpp
bool mstring::ReadLine(FILE * unit)
bool mstring::ReadLine(istream unit)
```

The next line from the file designated by "unit" is read into the invoking object of **mstring**. Carriage-returns and line-feeds are removed. The maximum length line that can be read is STR_MAX. Returns 'true' if the operation succeeded, 'false' otherwise or if end of file.
9.2.3.25 SymGet()

| mstring SymGet(mstring name)          |
| mstring SymGet(char * name)           |
| mstring SymGet(global name)           |
| mstring SymPut(name, value)           |

These functions retrieve and store values from/to the run-time symbol table. In all, name is a string containing the name of the variable and value is the value to be stored. The SymPut() functions return true if successful. A MumpsSymbolTableException exception is raised if SymGet() fails. If SymPut() fails, the program terminates (out of memory). For SymPut(), 'name' and 'value' may be any combination of mstring, global or .

9.2.3.26 Token()

| mstring Token()                   |
| mstring TokenInit(mstring)        |

Token() returns the next word token from the input string. Initially a line of text is passed to TokenInit(). For each subsequent call to Token(), the next lexical token from the original string is returned. Upper case letters are converted to lower case letters. When there are no more words, the empty string is returned. After the empty string is returned (or when initially called), the function will accept and store a new line of text.

9.2.3.27 ScanAlnum()

| mstring ScanAlnum(FILE * file [,int min [int max]]) |
| mstring ScanAlnum(istream file [,int min [int max]]) |

Returns the next token from the input file with all punctuation removed. Returns empty string on end of file. If min and/or max are provided, only words whose length are less than min and greater than max are discarded. The default values for these parameters are 3 and 25, respectively. Use stdin for file to scan standard input.

9.2.3.28 Stem()

| mstring Stem(mstring word) |

The function returns the word stem of the argument word or the original word if none can be calculated.

9.3 Miscellaneous functions

9.3.1 Boyer-Moore-Gosper Functions

| int bmg_fullsearch(mstring search_string, mstring buffer_base) |

Returns the number of non-overlapping instances of "search_string" in "buffer_base".

Examples:

```c
#include <mumpsc/libmpscpp.h>

int main() {

mstring a="now is the time for all good men to come to the aid of the party";
mstring b="to";
cout << bmg_fullsearch(b,a) << endl;
return EXIT_SUCCESS;
}
```
These functions are publically available from:

and are believed to be contributed source and are unrestricted with respect to use and
redistribution, and, that most, if not all, the code was written by employee(s) of the United States and
thus in the public domain. The distribution contains, in part, the following notes:

Here are routines to perform fast string searches using the
Boyer-Moore-Gosper algorithm; they can be used in any Unix program (and
should be portable to non-Unix systems). You can search either a file
or a buffer in memory.

The code is mostly due to James A. Woods (jaw@ames-aurora.arpa)
although I have modified it heavily, so all bugs are my fault. The
original code is from his sped-up version of egrep, recently posted on
mod.sources and available via anonymous FTP from ames-aurora.arpa as
pub/egrep.one and pub/egrep.two. That code handles regular
expressions; mine does not.

These have only been tested on 4.2BSD Vax systems.

BMGSUBS(3L) BMGSUBS(3L)

NAME
   (bmgsubs) bmg_setup, bmg_search, bmg_fsearch - Boyer-Moore-Gosper
   string search routines

SYNOPSIS
   bmg_setup(search_string, case_fold_flag)
   char *search_string;
   int case_fold_flag;

   bmg_fsearch(file_des, action_func)
   int file_des;
   int (*action_func)();

   bmg_search(buffer_base, buffer_length, action_func)
   char *buffer_base;
   int buffer_length;
   int (*action_func)();

DESCRIPTION
   These routines perform fast searches for strings, using the Boyer-
   Moore-Gosper algorithm. No meta-characters (such as `*` or `.'') are
   interpreted, and the search string cannot contain newlines.

   Bmg_setup must be called as the first step in performing a search. The
   search_string parameter is the string to be searched for.
   Case_fold_flag should be false (zero) if characters should match
   exactly, and true (non-zero) if case should be ignored when checking
for matches.

Once a search string has been specified using bmg_setup, one or more searches for that string may be performed.

Bmg_fsearch searches a file, open for reading on file descriptor file_des (this is not a stdio file.) For each line that contains the search string, bmg_fsearch will call the action_func function specified by the caller as action_func(matching_line, byte_offset). The matching_line parameter is a (char *) pointer to a temporary copy of the line; byte_offset is the offset from the beginning of the file to the first occurrence of the search string in that line. Action_func should return true (non-zero) if the search should continue, or false (zero) if the search should terminate at this point.

Bmg_search is like bmg_fsearch, except that instead of searching a file, it searches the buffer pointed to by buffer_base; buffer_length specifies the number of bytes in the buffer. The byte_offset parameter to action_func gives the offset from the beginning of the buffer.

If the user merely wants the matching lines printed on the standard output, the action_func parameter to bmg_fsearch or bmg_search can be NULL.

AUTHOR
Jeffrey Mogul (Stanford University), based on code written by James A. Woods (NASA Ames)

BUGS
Might be nice to have a version of this that handles regular expressions.

There are large, but finite, limits on the length of both pattern strings and text lines. When these limits are exceeded, all bets are off.

The string pointer passed to action_func points to a temporary copy of the matching line, and must be copied elsewhere before action_func returns.

Bmg_search does not permanently modify the buffer in any way, but during its execution (and therefore when action_func is called), the last byte of the buffer may be temporarily changed.

The Boyer-Moore algorithm cannot find lines that do not contain a given pattern (like "grep -v") or count lines ("grep -n"). Although it is fast even for short search strings, it gets faster as the search string length increases.

16 May 1986           BMGSUBS(3L)

9.3.2 cvt()

char *cvt(long i)
char *cvt(double i)
char *cvt(float i)
char *cvt(int i)
These functions return a null terminated varying length character string containing in printable version of the argument. The functions contain short static character arrays and, consequently, are not threadsafe.

9.3.3 xecute() and command()

`command()` is a macro that takes a quoted string constant argument. The macro surrounds the string with an extra set of quotes and processes any embedded quotes to backslash-quote. It then invokes a function `_command_()` which strips the extra surrounding quotes. The net effect of this is that you can pass a quoted string containing quotes without the need for "leaning toothpick" notation. Example:

```c
xecute(command("for i=1:1:10 "test ",i,!"));
strcpy(target, command("for i=1:1:10 write "test ",i,!"))
```

The argument must be a character string constant.

9.3.4 ErrorMessage()

```c
void ErrorMessage(char * message, int line_number)
```

This function (written in C and part of the underlying legacy library) will print and error message, close the global array files and terminate the program. The integer "line_number" will be printed with the message. The pre-processor predefined macro "__LINE__" can be used here. Example:

```c
ErrorMessage("Cannot locate patient", __LINE__);
```

9.3.5 Error Exceptions

The toolkit generates (throws) exceptions for certain conditions. For example, when you access global arrays with the toolkit, the accesses may result in the thrown error exceptions:

1. ConversionException.
2. GlobalNotFoundException
3. MumpsSymbolTableException.

The first can occur in any context that attempts to retrieve data from a global array where none exists. The second occurs if you attempt to convert the contents of a global to a numeric type where the contents of the global are not valid data for the conversion.

If uncaught, both exceptions will result in program termination.

The following are the exceptions thrown by the toolkit:

1. ConversionException() - usually occurs when you attempt to store a value from a global array into a numeric variable but the string in the global is not a valid number.
2. GlobalNotFoundException() - thrown by an attempt to reference non-existent global array data.
3. MumpsSymbolTableException() - thrown by an attempt to fetch the value of a non-existent variable from the Mumps runtime symbol table.
4. NumericRangeException() - thrown by attempts to divide by zero or using arguments with values less that or equal to zero to log functions.

```c
#include <mumpsc/libmpsc++h>
global a("a");

int main() {
    long i;
    a().Kill();
    mstring A;
    a("1") = "now is the time";
    try {
        i = a("1");
    }
```
catch (ConversionException ce) {
    cout << ce.what() << endl;
}
try {
    i = a("22");
}
catch (GlobalNotFoundException nf) {
    cout << nf.what() << endl;
}
try {
    A=SymGet("abc");
}
catch (MumpsSymbolTableException st) {
    cout << st.what() << endl;
}
return 0;

9.3.6 HitRatio()

```c
double HitRatio(void)
```

Calculates the native global array processor cache hit ratio since the beginning of the program or the last call to HitRatio(). The native global array file processor, as opposed to the Berkeley Data Base, keeps track of how many file I/O requests are satisfied from data already in the file system's cache. This function gives the percentage of cache hits. It only works with the native global array processor.

9.3.7 Hashing functions

```c
char * hash(char * str)
long lhash(char * str)
```

`hash()` returns either a null terminated character string up to 10 characters in length containing a numeric hash code of the string passed as an argument. The argument may be up to `STR_MAX` characters in length. `lhash()` returns an `unsigned long` value of the hash value.

9.3.8 Dump Global Array Database

```c
void Dump(char * filename)
void Dump(mstring filename)
void Dump(string filename)
void Restore(char * filename)
void Restore(mstring filename)
void Restore(string filename)
```

The global array database is dumped (written in its entirety) to `filename` or read and restored from `filename` (null terminated array of chars). Both operations must not be done from the same program.

9.3.9 Stream Output

```c
friend ostream & operator << (ostream&, global)
```

A global array may participate in stream output. For example:
gbl("A","B","C") << "test test test";
cout << gbl("A","B","C") << endl;

The above will print "test test test" (without quotes) followed by the newline character. Alternatively:
cout << gbl("A","B","C").Get() << endl;

will do the same thing (the Get() function returns "char *").

9.3.10 Smith-Waterman Alignment Function

```
int sw(mstring s, mstring t, [int show_aligns=0, int show_mat=0, int gap=-1, int mismatch=-1, int match=2])
int sw(string s, string t, [int show_aligns=0, int show_mat=0, int gap=-1, int mismatch=-1, int match=2])
int sw(char *s, char *t, [int show_aligns=0, int show_mat=0, int gap=-1, int mismatch=-1, int match=2])
```

Calculate the Smith-Waterman Alignment between strings "s" and "t". Result returned is the highest alignment score achieved. Parameters other than the first two are optional. If only some of the optional parameters are supplied, only trailing parameters may be omitted, as per C/C++ rules.

If you compare very long strings (>100,000 character), you may exceed stack space. This can be increased under Linux with the command:

```
ulimit -s unlimited
```

(Other options are ulimit -a and ulimit -aH to show limits).

If "show_aligns" is zero, no printout of alternative alignments is produced (default). If "show_aligns" is not zero, a summary of the alternative alignments will be printed. If "show_mat" is zero, intermediate matrices will not be printed (default). The gap and mismatch penalties are -1 and the match reward is +2. The parameters "gap", "mismatch" and "match" are the gap and mismatch penalties (negative integers) and the match reward (a positive integer). These values default to -1,-1 and 2 respectively. If insufficient memory is available, a segmentation violation will be raised.

The first character of each sequence string MUST be blank.

Example:

```
#include <mumps/libmumps++.h>

int main() {

    char s[]=" now is the time for all good men to come to the aid of the party";
    char t[]=" time for good men"

    int i=sw(s,t,1,0,-1,-1,3);

    return 0;
}
```

results in:

S-W Alignments for:
64 now is the time for all good men to come to the aid of the party
22 time for good men
29 men 32
::::

58
9.3.11 Stop list functions: StopInit(), StopLookup()

```plaintext
void StopInit(mstring file)
void StopInit(string file)
void StopInit(char * file)

int StopLookup(mstring word)
int StopLookup(string word)
int StopLookup(char * word)
```

*StopInit()* reads the sorted file "file" of stoplist words into the stoplist container (one word per line). *StopLookup()* returns 0 if "word" is not found and 1 if "word" is found in the stoplist.

9.3.12 Synonym Functions: SymInit(), SYN()

```plaintext
int SymInit(mstring filename)
int SymInit(string filename)
int SymInit(char * filename)

mstring SYN(mstring word)
string SYN(string word)
char * SYN(char * word)
```

*SysInit()* opens and reads a synonym file and returns the number of lines read. The maximum number of synonyms permitted is determined by "SYNMAX" in *libmpscpp.h* (default is 20,000). Each line of the synonym file consists of multiple words, in lower case, separated from one another by a single blank. The first word is the root alias and the remaining words are alternative synonyms. The function *SYN()* looks up a word. If the word is an alternative synonym, the root alias is returned. If not, the original word is returned.
9.3.13 int $test

Returns integer 1 or 0 indicating the success or failure of certain previous commands. Some, but not all, commands set "$test".

9.3.14 Xecute()

```c
int Xecute(char * command)
int Xecute(mstring command)
int Xecute(string command)
int Xecute(char * command)
```

These functions invoke the Mumps interpreter which executes `command`. Returns 1 of successful, 0 otherwise.

The macro `Xecute()` is a special case. It is used with character string constants. It will pre-process a character string constant command and insert the backslash escape character prior to any embedded quotes thus permitting more normal appearing text (see similar macro `command()`).

Examples:

```c
mstring c;
Xecute("fors i=$Order(^a(i)) q:i=" s sum=sum+^a(i)");
c="for i=1:1:10 write i,";
xecute(c);
c=command("for i=1:1:10 write "ans="i,"");
xecute(c);
```

9.3.15 Zseek() Ztell()

```c
bool Zseek(FILE *file, offset)
bool Ztell(FILE *file, offset)
```

These functions are used in connection with direct access files opened with FILE pointers (see: `fopen()`). They are compatible with 64 bit file pointer systems. `Zseek()` positions the file designated by `file` to the offset specified in `offset`, a positive integer contained in a variable of type `mstring` or `global`.

`Ztell()` places the current file offset in the file designated by `file` into the `mstring` or global variable represented by `offset`.

Both functions return 'true' if successful. Ordinarily, file offsets will be obtained by `Ztell()` and these will be stored in a data base. These values will be subsequently used in connection with `Zseek()` to reposition the file to the point it was at when the `Ztell()` was performed. After re-positioning, the next input or output operation on the file will occur at the point designated by `offset`. All offsets are relative to the start of the file.

10 Appendix A

10.1 Code Examples

The following are examples constitute an information storage and retrieval system that reads the file osu.medline ( OHSUMED collection of medical journal abstracts used in TREC-9. The Linux/Cygwin script file is shown first.

```c
// #+++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++++
// #+
// #+ Mumps ISR Software Library
```
MDH-reformatX.cpp Feb 27, 2007

#include <mumpsc/libmpscpp.h>

global doc("doc");

int main() {

FILE *ul;

ul = fopen("osu.medline","r");
assert (ul != 0);

mstring line, D, off;

D = 0;

while (1) {
    Ztell(ul, off);
    if (! line.ReadLine(ul) ) break;
    if ( line.Extract(1,2) == "TI") {
        D=D+1;
        doc(D) = off;
        cout << line.Extract(7,1023) << endl;
        continue;
    }
    if (line.Extract(1,2) != "AB") continue;
    cout << line.Extract(7,1023) << " ";
    while (1) { // for each line of the abstract
        if (! line.ReadLine(ul)) break;
    }
}
if (line.Length() == 0) break;
    cout << line.Extract(7, 255) << " ";
}  
    cout << endl;
}  
GlobalClose;
return EXIT_SUCCESS;
}

11.1 Perl Compatible Regular Expression Library License

Programs written with the MDH may call upon the Perl Compatible Regular Expression Library. In some cases, this library is distributed with the Mumps Compiler. The PCRE Library is not covered by the GNU GPL/LGPL Licenses but, rather, by the license shown below. The following is the PCRE license:

PCRE LICENCE
----------
PCRE is a library of functions to support regular expressions whose syntax and semantics are as close as possible to those of the Perl 5 language. Written by: Philip Hazel
University of Cambridge Computing Service,
Copyright (c) 1997-2001 University of Cambridge
Permission is granted to anyone to use this software for any purpose on any computer system, and to redistribute it freely, subject to the following restrictions:
1. This software is distributed in the hope that it will be useful, but WITHOUT ANY WARRANTY; without even the implied warranty of MERCHANTABILITY or FITNESS FOR A PARTICULAR PURPOSE.
2. The origin of this software must not be misrepresented, either by explicit claim or by omission. In practice, this means that if you use PCRE in software which you distribute to others, commercially or otherwise, you must put a sentence like this
   Regular expression support is provided by the PCRE library package, which is open source software, written by Philip Hazel, and copyright by the University of Cambridge, England.
somewhere reasonably visible in your documentation and in any relevant files or online help data or similar. A reference to the ftp site for the source, that is, to ftp://ftp.csx.cam.ac.uk/pub/software/programming/pcre/ should also be given in the documentation.
3. Altered versions must be plainly marked as such, and must not be misrepresented as being the original software.

12.1 Using Perl Regular Expressions

Author: Matthew Lockner

In addition to Mumps 95 pattern matching using the "?" operator, it is also possible to perform pattern matching against Perl regular expressions via the perlmatch function. Support for this functionality is provided by the Perl-Compatible Regular Expressions library (PCRE), which supports a majority of the functionality found in Perl's regular expression engine.

The perlmatch function works in a somewhat similar fashion to the '?' operator. It is provided with a subject string and a Perl pattern against which to match the subject. The result of the function is boolean and may be used in boolean expression contexts such as the "If" statement.

Some subtleties that differ significantly from Mumps pattern matching should be noted:

1. A Mumps match expects that the pattern will match against the entire subject string, in that successful matching implies that no characters are left unmatched even if the pattern matched against an initial segment of the subject string. Using perlmatch, it is sufficient that the entire Perl pattern matches an initial segment of the subject string to return a successful match.

2. The perlmatch function has the side effect of creating variables in the local symbol table to hold backreferences, the equivalent concept of $1, $2, $3, ... in Perl. Up to nine backreferences are currently supported, and can be accessed through the same naming scheme as Perl ($1 through $9). These variables remain defined up to a subsequent call to perlmatch, at which point they are replaced by the backreferences captured from that invocation. Undefined backreferences are cleared between invocations; that is, if a match operation captured five backreferences, then $6 through $9 will contain the null string.

12.2 Examples

This program asks the user to input a telephone number. If the data entered looks like a valid telephone number, it extracts and prints the area code portion using a backreference; otherwise, it prints a failure message and exits.

```
Zmain
Write "Please enter a telephone number:",!
Read phonenum
If $$^perlmatch(phonenum,"^(1­)?\((?d{3}\)?)?(­| )?\d{3}­?\d{4}$") Do
  . Write "+++ This looks like a phone number.",!
  . Write "The area code is: ",$2,!
Else  Do
  . Write "--- This didn't look like a phone number.",!
Halt
```

The output of several sample runs of the program follows:

Please enter a telephone number:
As in Perl, sections of the regular expression contained in parentheses define what is contained in the backreferences following a match operation. The backreference variables are named in a left-to-right order with respect to the expression, meaning that $1 is assigned the portion matched against the leftmost parenthesized section of the regular expression, with further references assigned names in increasing order. For a much more in-depth treatment of the subject of Perl regular expressions, refer to the perlre manpage distributed with the Perl language (also widely available online).

13 Appendix E

13.1 Mumps 95 Pattern Matching

Author: Matthew Lockner

Mumps 95 compliant pattern matching (the '?' operator) is implemented in this compiler as given by the following grammar:

```
pattern   ::= {pattern_atom}
pattern_atom ::= count pattern_element
count      ::= int | '.' int
| int '.' int
pattern_element ::= pattern_code {pattern_code} | string | alternation
pattern_code ::= 'A' | 'C' | 'E' | 'L' | 'N' | 'P' | 'U'
alternation ::= '(' pattern_atom {',' pattern_atom} ')'```

The largest difference between the current and previous standard is the introduction of the alternation construct, an extension that works as in other popular regular expressions implementations. It allows for one of many possible pattern fragments to match a given portion of subject text.

A string literal must be quoted. Also note that alternations are only allowed to contain pattern atoms and not full patterns; while this is a possible shortcoming, it is in accordance with the standard. It is a trivial matter to extend alternations to the ability to contain full patterns, and this may be implemented upon sufficient demand.

Pattern matching is supported by the Perl-Compatible Regular Expressions library (PCRE). Mumps patterns are translated via a recursive-descent parser in the Mumps library into a form consistent with Perl regular expressions, where PCRE then does the actual work of matching. Internally, much of this translation is simple character-level transliteration (substituting '|' for the comma in alternation lists, for example). Pattern code sequences are supported using the POSIX character classes supported in PCRE and are mostly intuitive, with the possible exception of 'E', which
is substituted with \[:print][:cntrl:]. Currently, this construct should cover the ASCII 7-bit character set (lower ASCII).

Due to the heavy string-handling requirements of the pattern translation process, this module uses a separate set of string-handling functions built on top of the C standard string functions, using no dynamic memory allocation and fixed-length buffers for all operations whose length is given by the constant STR_MAX in sysparsms.h. If an operation overflows during the execution of a Mumps compiled binary, a diagnostic is output to stderr and the program terminates. If such termination occurs too frequently, simpl
